Method was made possible by the ability of micro-PB to accept nonvolatile HPLC modifiers. Less than 0.1 ppb of several pesticides was detected in tap water using this procedure.

6.4 Atmospheric Pressure Chemical Ionization Interface

The applicability of APCI is similar to that offered by PB and has been demonstrated in several reports to be particularly suitable for pesticide analysis. The APCI interface was compared with other LC interfaces (TSP, IS, PB) in a study on the determination of N-methylcarbamates in pepper extracts.\(^{52}\) TSP, working in the PI filament-on, mode provided good sensitivity, although some fluctuation of the ion signal perturbed the analyses. Further fragmentation could be induced for enhanced confirmatory capabilities. The PB interface used in this work was a conventional one and was mounted on the same mass spectrometer as utilized for TSP. In this configuration, the PB performance was not satisfactory, mainly because the transport of the analytes into the ion source was inefficient. The performance of IS was comparable to that of TSP, providing mainly protonated molecules, although more information can be obtained by varying the cone voltage. CID will allow further structure elucidation. APCI with a heated nebulizer permits both protonated molecules and fragment ions. API techniques, besides their ease of use, are complementary and readily interchangeable, allowing a wide range of compounds with different chemical properties to be analyzed (Figure 12a–g).

Figure 12 Background-subtracted flow injection analysis (FIA) spectra of methomyl obtained by IS/MS (250 ng) at OR (a) 50 V and (b) 70 V, (c) IS/MS/MS (250 ng), (d) APCI/MS (50 ng), (e) PB/CI (2 µg), (f) PB/EI (2 µg) and (g) TS/MS (250 ng). (Reprinted by permission of Elsevier Science from S. Pleasance, J.F. Anacleto, M.R. Bailey, D.H. North, ‘An Evaluation of Atmospheric Pressure Ionization Techniques for the Analysis of N-Methylcarbamate Pesticides by Liquid Chromatography Mass Spectrometry’, *J. Am. Soc. Mass Spectrom.*, 3, 378 (1992). Copyright 1992 by American Society for Mass Spectrometry.)
Ten different pesticides were determined in extracts of strawberries and plums. In order to select the most suitable LC/MS technique, an initial comparison between APCI and ES was made. Spectra of the selected compounds were acquired using APCI and ES in both PI and NI modes, obtaining similar spectra, although for most compounds with ES the most significant ion was the sodium adduct ion. Limits of detection were comparable for most compounds with the two techniques, but APCI was more sensitive for aldicarb and its metabolites. For this reason and for greater flexibility with LC flow rates, APCI was the interface chosen. This method allowed detection limits as low as 0.02 mg kg$^{-1}$ to be achieved for most compounds, meeting Codex Alimentarius Commission requirements.

APCI/MS (APCI/MS/MS) coupled with single, short LC columns was successfully used for the determination of several pesticides and herbicides in tap and river water. The short column allowed fast separation of the analytes, increasing sample throughput. The protonated molecules generated by the APCI interface were subjected to CID for structure elucidation and for the confirmation of target and unknown compounds. This instrumentation has been used to obtain CID spectral data in the PI mode with the purpose of building a spectral library. The same approach was used to analyze 17 different pesticides belonging to six different classes in aqueous samples. A comparison between APCI and IS was also performed. The two interfaces were operated under the same conditions, with no volatile acids added to the mobile phase. The two interfaces performed similarly in terms of limits of detection (0.1–50 ng in full-scan mode for 12 of the 17 pesticides. Two of the investigated compounds, fenchlorphos and bromophos-ethyl, were detected by neither interface. In order to facilitate interpretation of the spectra, an MS/MS library of the product-ion spectra of protonated molecules was produced. The recording of the spectra of 73 pesticides and their metabolites was accomplished first in the PI full-scan mode and then, with [M + H]$^+$ ions selected as precursor ions, in the MS/MS product-ion mode.

An automated on-line SPE/LC/APCI system was used for the analysis of organophosphorus pesticides in groundwater and triazine and phenylurea herbicides in miscellaneous environmental matrices.

REFERENCES

Immunochemical assays (immunoassays, IAs) are biochemical assays which work according to the law of mass action. They are based on the recognition of an antigen (Ag) or a hapten by antibodies (Abs). Abs are serum glycoproteins of the immunoglobulin (Ig) class and are produced by the vertebrate immune system against foreign material of high molecular mass. The result of the binding reaction between the Ab and an analyte is usually made visible by means of enzymatic, chemiluminescent, fluorescent or radioactive markers. According to the label used IAs can be classified into enzyme immunoassays (EIAs), radioimmunoassays (RIAs), fluorescence immunoassays (FIAs) or chemiluminescent immunoassays (CLIs). The measuring range of most IAs for pesticides is in the parts per trillion to lower parts per billion range. A lot of samples can be analyzed within a short time, while only low sample volumes are necessary. In many cases (water, some liquid food samples) no extraction step and no cleanup are necessary. Not all assays are completely specific to one single compound. Cross-reactivities of the Abs with haptens similar to the analyte can be observed. In some cases, matrix effects may occur, especially with soil or colored food extracts. Therefore, validation of the assays for the matrix of interest should be carried out. As IAs are usually targeted at a single analyte or a group of analytes, multi-analyte approaches using Ab arrays or a combination of immunochemical techniques with liquid chromatography (LC) are pursued.

1 INTRODUCTION

Interest in immunochemical assays for the determination of pesticides has been steadily increasing. IAs are now commonly applied for the analysis of contaminants in water, soil, food and body fluids. The first immunological experiments had already been carried out as early as the late eighteenth century when Edward Jenner, an English physician, used cowpox to prevent infection with smallpox. Based on these studies Louis Pasteur developed the use of attenuated strains of microorganisms for successful vaccinations. Emile Roux and Alexandre Yersin then found that immunity is caused by soluble compounds of microorganisms, which they called toxins. These toxins induce specific compounds in the immunized animal, which were named “antitoxins” by Emil von Behring and Shibasaburo Kitasato (1890) and are now called Abs. The Ab “generating” compounds are known as Ags.

Around the turn of the century it was shown that Abs are not only produced against microorganisms and their toxins, but also by other substances such as milk, protein or plant-derived toxins. Paul Ehrlich was the first to carry out quantitative studies on Ag–Ab interactions. The great interest in this field led to the first book on immunochemistry, published by Svante Arrhenius in 1907. Karl Landsteiner also belongs to the pioneers in immunochemistry. He systematically used small artificial molecules, which he called haptens, coupled to a carrier molecule for immunization. In 1923 Heidelberger and co-workers found polysaccharides to be antigenic as well. Studies by Rodney Porter (1959) and Gerald Edelman (1961) have provided the chemical structure of the Ab molecule. The enormous variety of Abs was explained by Frank McFarlane Burnet in 1957, based on a hypothesis of Niels Jerne dating from 1955, the now widely accepted clonal-selection theory. It describes each Ab-producing
cell as carrying on its surface only one type of Ab as a receptor. The binding of a respective Ag to this receptor leads to a clonal expansion of this cell and to the maturation of Ab-producing cells.

Immunochemical methods have their origin in the medical field. The first IA, a RIA for the quantification of insulin in serum, was described by Yalow and Berson.(11) Later, radiolabels were replaced by enzymes in EIAs by Engvall and Perlmann(12) and Van Weeman and Schuurs.(13) Since then radiolabels have obtained broad application in medical diagnostics and environmental analysis.

IAs belong to the most common methodology in the field of immunoanalysis. Even though Abs are (still) produced by a biological process, IAs are nevertheless chemical analytical procedures. The basic principle applying to all immunoreactions is based upon the law of mass action. In the equilibrium reaction between a free Ag or a hapten, such as a pesticide, and the Ab forming the hapten–Ab complex HAb (=bound hapten), represented by Equation (1),

\[ H + Ab = HAb \]  

the affinity constant \( K \) determines the concentration ratio between the bound hapten and the free reaction partners, Equation (2):

\[ K = \frac{[HAb]}{[H][Ab]} \text{mol}^{-1} \]  

A low detection limit (DL) in an IA therefore requires a high affinity of the Ab toward the analyte, which is expressed by a high affinity constant. For further details refer to Hock et al.(14)

IAs are based upon the measurement of Ab binding-site occupancy by the analyte (Figure 1). This reflects the analyte concentration in the sample. Since the binding reaction does not produce a signal which can be detected by simple means, various markers, e.g. radioactivity, enzymes, or fluorescence, are employed for the detection of the immunoreaction (see section 3.2). However, more sophisticated techniques like some immunosensing methods do not rely on a label (see section 6).

2 ANTIBODIES

2.1 Antibody Structure

Immunochromical analysis is based upon the specific reaction between an Ab and its corresponding Ag or hapten. Abs are part of the vertebrate defense system (for more details refer to immunology textbooks, for example Golub(15) and Roitt.(16) They are serum glycoproteins of the Ig class produced by the immune system against foreign material such as pathogens or xenobiotics, and bind the target substance with high selectivity and affinity. Although there are five distinct classes of Ab in most higher mammals (IgA, IgD, IgE, IgG, IgM) IgG makes up approximately 80% of the total Ig in human serum. Most IAs rely upon IgG as the major Ig.

The basic structure of an Ab molecule is shown in Figure 2. It consists of two identical heavy (H) chains and two identical light (L) chains stabilized and linked by inter- and intrachain disulfide bonds. The H- and L-chains are organized into variable and constant regions. The Ag binding site (combining site) is formed by the association of parts of the variable regions of the H- and L-chains, located at the amino terminal end. The variable regions of both chains are organized into three
hypervariable or complementarity determining regions (CDRs) separated by four framework regions. The greatest amino acid sequence variation occurs within the CDRs whereas the framework regions are more conserved. It is assumed that the association of the CDR regions forms the combining site. The lower part of the molecule, the Fc (antibody fragment containing the crystallizable fragment) is responsible for some important biological effector functions such as complement fixation and is not necessary for Ag or hapten binding. It contains the last heavy chain domains. The whole of the Ig molecule or Ab fragments, F(ab)_2 and Fab (antibody fragments containing the antigen binding site(s)) can be used in IAs.

A substance that after injection into the body of a vertebrate induces a specific Ab synthesis, is called an Ag. Ags are principally macromolecules, for instance proteins, polysaccharides or nucleic acids. Synthetic polymers also belong to the antigens, i.e. they can be used as, or act as, Ags. Small molecules (haptens) such as pesticides have to be coupled to a macromolecular carrier to elicit an Ab response (see section 2.3). The ability of an Ab molecule to bind an Ag or a hapten specifically is controlled by the nature of the Ag–Ab binding process. Therefore, the selectivity and sensitivity of an IA is controlled by the nature of the Ag–Ab binding process.

2.2 Antibody Production

Ab production is conveniently carried out in warm blooded animals, e.g. rabbits, sheep, mice or chickens. Polyclonal antibodies (pAbs) are obtained from the serum and comprise a mixture of different Ag populations. Monoclonal antibodies (mAbs) consist of a single monospecific Ag population. These Abs are produced in cell culture by a single hybridoma cell derived from the fusion of B-lymphocytes with myeloma cells. The hybridoma cells can then be propagated almost indefinitely in culture and will continue to produce the Ab of the lymphocyte parent. Since an individual lymphocyte produces only a single Ab type, all of the Ab molecules produced by a hybridoma cell line derived from a single hybrid cell are identical and have the same binding properties. Therefore, the hybridoma technology guarantees the unlimited production of mAbs with constant characteristics. Owing to the great effort involved in mAb production many IAs still employ pAb. A third possibility for creating Abs has emerged, recombinant antibody (rAb) techniques. Here, Ig genes can be cloned, introduced and expressed in inexpensive and relatively simple host systems. Although several nonmammalian host systems (yeast, plant and insect cells) have been used to produce rAbs, the most common vehicle is Escherichia coli. The main properties of pAbs, mAbs and rAbs are listed in Table 1.

2.3 Immunogens

Most pesticides are of low molecular mass and therefore are not ordinarily antigenic. They have to be coupled to a carrier molecule, usually a protein, in order to induce an Ab response in the vertebrate immune system. The site of coupling to the carrier, the coupling procedure as well as the number of haptens bound to one carrier molecule can be of major importance for the sensitivity and the selectivity of the resulting Ab (for reviews refer to Erlanger, Goodrow et al. and Szurdoki et al.). The protein carriers used in various laboratories include globulin fractions, serum albumins of different species, hemocyanin, ovalbumin, thyroglobulin, and fibrinogen. Also nonproteinaceous carriers have been used such as liposomes or dextran. Keyhole limpet hemocyanin (KLH), a protein from mollusks, is often viewed

\[ \pi-\pi \] electron interaction, and van der Waals forces. The binding energy (relative affinity of the Ab) increases with the number of specific chemical interactions between the analyte and the amino acid residues in the Ab combining site. Therefore, the selectivity and sensitivity of an IA is controlled by the nature of the Ag–Ab binding process.
as a superior carrier because it is foreign to the vertebrate immune system.\(^{26}\)

Another important issue concerns the optimal number of haptens bound to the carrier protein (i.e. optimal epitope density). Highly substituted carriers usually lead to the best results. For bovine serum albumin (BSA) molar ratios of 10:1 to 20:1 (hapten:carrier) are desirable; for larger molecules such as hemocyanin, ratios of 800:1 to 1000:1 should be obtained.\(^{17}\) However, very high ratios may reduce immunogenicity because of either the changes in tertiary structure of the protein caused by masking of the essential free amino groups or the removal of critical determinant sites on the carrier by haptenic blocking.

For the production of pAbs the purity of the hapten used to prepare an immunoconjugate should be as high as possible. After synthesis of haptenic substances, closely related substances may be present in small quantities, leading to the production of nonspecific Abs and, consequently, to unwanted cross-reactivities of the antisera. This is not a problem with mAb, because a single cell line producing only one kind of Ab with the desired properties can be selected.

Another important consideration is the point of attachment on the hapten. Ab specificity is directed primarily at the part of the hapten molecule farthest away from the functional group that is linked to the protein carrier.\(^{26}\) Even better specificity can be obtained with conjugates in which the hapten is coupled to the carrier via a spacer, thereby giving much better exposure of the hapten on the surface of the carrier. The spacer should be attached as far as possible from the unique determinant structures.\(^{26}\) Usually C\(_3\)–C\(_5\) spacers are used; if the spacer is too long, it may bend back to the carrier and the hapten will not be properly exposed. Strategies for IA hapten design for the triazine, ary lurea and chloroacetanilide herbicides have been summarized by Goodrow et al.\(^{26}\)

The functional groups of the hapten govern the selection of the method to be used to conjugate the hapten to the functional groups of the carrier. The functional groups of the protein carrier available for attachment of the haptens are the carboxyl group of the C terminal and of the aspartic and glutamic acid residues, the amino group of the N terminal and the lysine residues, the imidazol and phenolic functions of the histidine and tyrosine residues, respectively, and the sulphydryl group of cysteine residues. General procedures for the preparation of conjugates can be found in Erlanger.\(^{24,25}\)

After coupling, characterization of the conjugates can be carried out (see Erlanger\(^{25}\)). Generally, the haptenic groups have an absorbance spectrum that can be differentiated from the protein carrier. Elemental analysis for the chlorine content can be carried out for some triazine conjugates. A more direct procedure is the incorporation of some radioactive hapten in the conjugation procedure. Another approach is quantitating the change in free amino groups as a result of conjugation. A recently applied technique is the determination of hapten density by matrix-assisted ultraviolet laser desorption/ionization mass spectrometry (MALDIMS)\(^{31}\) and electrospray ionization mass spectrometry (ESIMS).\(^3\)

Application of energy-minimized molecular modeling methods to hapten design will help to choose the best derivatives and conjugation methods for successful Ab production.\(^{32}\)
3 IMMUNOASSAY TYPES

3.1 Assay Formats

For low-molecular-mass analytes (haptens) such as pesticides in solution, competitive tests have to be employed, using limiting Ab concentrations. The tests can be performed as homogeneous assays without separation of the reactants, but more common are heterogeneous tests where unreacted reagents are removed before evaluation. Two different formats are available, (1) with immobilized Ab (Figure 1a) and (2) with immobilized coating conjugate (Figure 1b). In variant (1) analyte and a labeled analyte (tracer) compete for the free Ab binding sites. After removal of unbound reactants the bound tracer yields a signal that is inversely proportional to the analyte concentration. The variant (2) employs an immobilized hapten-carrier conjugate on the solid phase to which analyte and Ab are added. The Ab binds to the free analyte or to the immobilized hapten according to the concentration of the reactants. If a labeled Ab is used, the amount of Ab bound to the solid phase can be directly determined after a washing step. Alternatively, a secondary labeled Ab may be used to detect the Ab which has bound to the solid phase. The signal is inversely proportional to the amount of free analyte in the sample. Very sensitive competitive IAs have been developed with DLs between 1 and 50 ng L$^{-1}$, for example for the triazines and urea herbicides.

An example for a homogeneous assay system is the polarization fluoroimmunoassay (PFIA). PFIA measures the increased polarization of fluorescence when a fluorophore-labeled hapten (tracer) is bound by a specific Ab, and the decreased signal when free analyte competes with the tracer for binding. While these assays are easy to carry out and very suitable for automation, they usually show a lower sensitivity than EIAs, e.g. for simazine a DL of 5 µg L$^{-1}$ was observed.

Noncompetitive assays can only be applied for high-molecular-mass analytes with more than one antigenic determinant (i.e. Ag) or low-molecular-mass analytes (haptens) bound to a solid phase, exposing the antigenic determinant. They work with an Ab excess. Noncompetitive IAs have been employed for the detection of soil-bound pesticides. In this case the soil particles, to which the pesticide residues have bound, form the solid phase, and the residues can be detected by a labeled Ab specific to the analyte.

3.2 Labels

Depending on the label, IAs are classified in different groups. Radioisotopes are used in RIAs, enzymes in enzyme-linked immunosorbent assays (ELISAs) or EIAs, fluorophores in FIA or PFIAs and chemiluminescent compounds in CLIs. Additional types of IA exist, but are not very common in pesticide analysis. A more detailed description of these IAs can be found in Gosling.

EIAs are most commonly used in pesticide analysis as they avoid the necessity of working with radioactive material and low DLs can be reached. Simple and cheap photometers which give an extremely rapid measurement capability and long-lasting stability of the colored product after the reaction has stopped make EIA superior to fluorimetry or luminometry, even though with these methods lower DLs may be reached.

Enzymes commonly used as labels in heterogeneous EIA are listed in Table 2.

The following requirements are necessary for the use of an enzyme as a marker:

1. high specific activity (turnover number) of free enzyme and after labeling,
2. availability of soluble, purified enzyme at low cost and reproducible quality,
3. high stability in free and conjugated form under storage and assay conditions,
4. presence of reactive groups for covalent linkage to hapten,
5. simple and gentle conjugation methods,
6. inexpensive and stable nontoxic substrates with formation of stable chromogenic, fluorogenic and/or chemiluminogenic products.

3.3 Solid Phases

IAs are mainly carried out in 96-well polystyrene, polyethylene, polypropylene or polyvinyl microtiter plates, owing to the easy separation of the reactants in a washing step, but polystyrene tubes, beads or pins are also available (Table 3). The plastic plates are of comparatively low binding capacity and low surface area to volume ratio. High-binding supports include agarose and cellulose. Particulate solid phases are very efficient, because they become scattered throughout the reaction mixture and have a much higher surface area to volume ratio. For example, many chemically different beads are available (e.g. polystyrene, latex, polycarbonate and copolymer beads). Immunological reagents are bound to the beads in a similar manner as they are to microtiter plates. Separation of bound and free reagents occurs by washing and centrifuging. IAs using magnetic beads employ a magnet for the separation step. Abs and Ags may be immobilized to some solid phases via covalent binding. Those solid supports contain amino or carboxyl groups on a modified surface through which the immunoreagents can be bound by water-soluble carbodi-imides or bifunctional reagents such as glutaraldehyde.

Other solid-phase supports for IAs are membranes. They can be used for dip sticks, which are incubated for a short time in the solution or for dot blot and immunofiltration tests. Here the reactants are filtered through the membrane. The test principle is the same as for the microtiter plate tests but the reaction time is much shorter owing to the high surface area of the membrane and the short distance between reaction partners. Application of remission measurements yields a proportional relationship between analyte and remitted light. By using a pocket reflectometer, this set-up is ideally suited for field-monitoring purposes.

4 PROPERTIES OF COMPETITIVE IMMUNOASSAYS

4.1 Dose–Response Curve

In IAs the signal produced is inversely correlated to the analyte concentration in the sample (Figure 3a). The typical dose–response curve is of sigmoidal shape when the signal is plotted versus the logarithm of the analyte concentration. A linear range is obtained around the middle of the test (IC50, middle of assay, concentration of analyte that causes 50% inhibition), which should be used for determinations. Within this working range, the change in absorbance is linearly correlated to the analyte concentration. The linear part of the curve is confined by the upper and lower limits of quantification. These are the cut-off values above or below which quantitative results can be obtained with a stated relative precision, or specified degree of confidence in real samples. The experimental errors increase toward these limits. Consequently, the most
precise measurements are obtained in the region close to the middle of the test.

The DL (or least detectable dose) is the smallest concentration of the analyte that produces a signal which can be significantly distinguished from zero for a given sample matrix with a stated degree of confidence. Very often a dose is selected which inhibits 10–20% of enzyme tracer from binding with the Ab or the dose calculated after subtraction of two or three times the standard deviation from the mean measurements of the zero dose signal.\(^3\)

Linearization of the calibration curve is useful for many purposes, for instance, for the direct comparison of curves if matrix effects are evaluated. Absorbance curves can be normalized by converting the absorptions to \(\%B/B_0\) values. These can be expressed as the ratio of bound tracer in the presence of hapten to bound tracer in the absence of hapten and lies between 100\% (\(=A_0\), the upper asymptote of the curve) and 0\% (\(=A_{\text{Excess}}\), the lower asymptote) (Figure 3b). They are calculated by Equation (3):

\[
\frac{\%B}{B_0} = \frac{A - A_{\text{Excess}}}{A_0 - A_{\text{Excess}}} \times 100 \quad (3)
\]

Linearization can be obtained by various mathematical transformations.\(^{47}\) Usually, IAs are evaluated with commercial IA programs, often based on logistic models (cf. Rodgers\(^{48}\) and Dudley et al.\(^{49}\)), e.g. four-parameter models or the more simple logit-log transformation (two-parameter model, Figure 3c) which can also be carried out with a calculator (s), Equation (4):

\[
\logit \frac{\%B}{B_0} = \ln \left(\frac{\%B/B_0}{100 - \%B/B_0}\right) \quad (4)
\]

4.2 Quality Control

Precision and accuracy of IA are important properties which deserve special attention. The quality and stability of the employed material (microtiter plates, pipettes) and reagents (e.g. Abs, enzyme tracer or buffers), play a crucial role.\(^{50}\) The long-term stability of reagents has to be ensured, e.g. by freeze-drying of Abs and, if necessary, addition of stabilizing components to the test reagents such as the enzyme tracer.\(^{51}\)

In spite of the simple handling of the assays, expert knowledge is required, especially to recognize and remove incident errors. Therefore, IAs should be performed by trained personnel. The development of simple and rapid assays, such as dip-stick assays or immunofiltration tests reduces the requirement for trained users, but one has still to be aware of potential problems such as interferences from the sample matrix.

The precision of an IA is defined as the extent to which replicate analyses of a sample agree with each other. The reproducibility is the ability to yield the same results within analyses, between analyses, and between operators. The investigation of the variability of an IA gives valuable information about the consistency of the test. Coefficients of variation (CV) of IA measurements are usually between 10 and 20\% for an optimized assay,\(^{52,53}\) although more precise results can be obtained.\(^{54,55}\) Same-day and day-to-day CV of samples have been determined in different matrices.\(^{53,56}\) Interlaboratory tests of the same IA as that carried out by Hock and the IA Study Group\(^{57}\) and Hayes et al.\(^{58}\) for the investigation of triazines help to evaluate the general applicability of a test. However, several conditions like exact description of the assay including calibration curves, DLs, cross-reactivities, a working range close to the middle of the
test, enough parallel measurements, etc. must be met (see also AOAC (Association of Official Analytical Chemists) criteria). Meanwhile, standardized procedures for IAs in water are adopted by AOAC International and have been established in Germany as a prenorm.\(^{50,58}\)

A validation of the results obtained by IA should be carried out. To a limited extent this can be done by IA itself. Dilution of the samples as well as spiking of the authentic sample with known amounts of the contaminant can be used to check whether the matrix interferes with the IA.\(^{59}\) However, spiked samples do not completely mimic real unknown samples. They do not contain potential metabolites of the contaminant nor residues from other compounds which may be present in real samples. Furthermore, spiked samples cannot be a model for aged residues which are more difficult to extract and detect because, for example, they may have bound to soil constituents. Therefore, an IA should also be validated by a different established method like high-performance liquid chromatography (HPLC), gas chromatography (GC) or GC/MS (gas chromatography/mass spectrometry). Many groups have used this approach and have usually obtained correlation coefficients of \(>0.9\).\(^{60–63}\) Often a slight overestimation of the IA in comparison with HPLC or GC is observed owing to cross-reactivities of the Ab or matrix effects.

### 4.3 Cross-reactivity

Depending on the conjugate used for immunization and the class of chemicals under investigation, cross-reactivities of the Ab with haptens similar to the analyte are frequently observed (see e.g. Hock\(^{14}\) and Harrison et al.\(^{64}\)). Therefore, it should be checked which compounds cross-react to what degree with the Ab. This is usually done by comparing the standard curves of the analyte under investigation with similar haptens, using analyte concentrations at 50% of the inhibition curve as the reference. However, cross-reactivity with a certain analyte is not the same over the whole range of a standard curve. Often higher cross-reactivities can be observed at low concentrations of the cross-reacting analyte.\(^{53}\) Therefore, it has been recommended that cross-reactivities be measured at different concentrations over the range where the assay is suitable.\(^{65}\)

If an Ab is selective for a single compound, it is regarded as monospecific\(^{66}\) (Figure 4). An Ab that recognizes several compounds to the same extent (e.g. a group of s-triazines), can be used for the screening of a class of herbicides\(^{67}\) (group-specific Ab, Figure 4). If cross-reacting compounds are not expected in the samples, because the compounds are not licensed (e.g. propazine in most European countries), a group-specific Ab can also be used for quantitative measurements of one compound.\(^{68}\)

![Figure 4](image-url) Selective, intermediate and group specific Abs. This example uses Abs which have been produced against hapten 1. Substances 2–5 are assumed to be cross-reacting haptens (modified after Hock et al.\(^{14}\)).

Strong cross-reactivities of an Ab to unexpected metabolites, for example, can produce false positive values. An Ab for alachlor was found to react very strongly to the sulfonic acid metabolite using an alachlor screening kit.\(^{69}\) This problem could be solved, however, by using solid-phase extraction (SPE) prior to IA and sequential elution of the two compounds with different organic solvents.

### 4.4 Sample Preparation and Matrix Effects

Samples can contain compounds in addition to the target analyte, which may interfere with the test. Several groups investigated the influence of ions on EIA\(^{s}\).\(^{70–72}\) Ruppert et al.\(^{70}\) observed an inhibition by several anions like azide, which inhibits the peroxidase by binding to the heme group of the enzyme. Most cations did not have an effect except for Ca\(^{2+}\), which leads to an activation of the peroxidase. No interference by different ions such as nitrate, copper, magnesium etc. up to a concentration of 250 ppm was detected in an EIA for pentachlorophenol in water.\(^{71}\) While ions may inhibit the enzyme used as a label or lead to precipitates by reacting with the buffer components, humic substances present in water or soil extracts may bind nonspecifically to the Ab and thereby interfere with the specific binding of the analyte.\(^{73}\) These reactions may lead to false positive results. Water samples from forest stands or soil extracts particularly contain a high content of organic compounds such as humic acids (HAs).

Matrix effects in food samples frequently occur owing to colored extracts or to the content of lipids, proteins or polyphenols that may be coextracted during sample preparation.\(^{74}\) As food samples usually have to be extracted prior to immunochemical analysis, the method of analyte extraction is of great importance. Analytes
that are water soluble and can be efficiently extracted in aqueous buffer will have the most direct extraction method and eliminate the need for organic solvents. However, many pesticides are not readily water soluble and must be extracted with an organic solvent.\(^{(5)}\) For the extraction of pesticides from solid foods a variety of solvents have been tested, such as acetone, ether, petroleum ether, methanol, acetonitrile or hexane.\(^{(75)}\) Direct analysis of extracts by IA requires the use of solvents that are miscible with water and (at low concentrations) are non-denaturing to proteins such as Ab. IAs are to a certain degree tolerant to a variety of solvents, but each system must be tested to determine which solvent can be accepted and to what extent (for example Hill et al.,\(^{(75)}\) Nugent\(^{(76)}\) and Schneider and Hammock\(^{(77)}\)). Usually the extracts are further diluted with water prior to the EIA, but an EIA for parathion was developed, in which the analyte dissolved in hexane could be directly measured in the EIA without prior removal of the hexane. This was achieved by using Ab encapsulated in reverse micelles composed of Aerosol T with aqueous centers.\(^{(78)}\) However, a \(10^4\)-fold decrease in sensitivity was observed.

In some cases a cleanup step is introduced, in which the analyte of interest is separated from the matrix. This can be carried out by \(C_{18}\)-columns or immunoaffinity columns.\(^{(69,79,80)}\) A very interesting approach is the application of supercritical fluid extraction (SFE) prior to immunoanalysis. These methods generally employ \(CO_2\) or \(CO_2\) containing various modifiers.\(^{(5,81)}\)

Some problems with interfering ions can be solved by changing the buffer of the assay system so that no precipitates may be formed.\(^{(70)}\) Addition of BSA to the plates prior to the addition of the standard and sample solutions\(^{(82)}\) or to the enzyme tracer\(^{(73)}\) greatly reduces the influence of humic and fulvic acids on the EIA. It may also be helpful to switch to a different batch of Abs or a different assay kit, as different Abs may show different sensitivities to interfering substances. The buffering capacity of the assay buffer should also be checked, as some water or food samples may show relatively low pH values. No effects, however, were observed between pH 3 and 10 by different investigators.\(^{(56,67,83)}\)

5 APPLICATION TO ENVIRONMENTAL SAMPLES

IAs have been developed for many environmental contaminants during the 1990s. A list of several IAs described in the literature can be found in Table 4. Most of them have been developed in laboratories, showing the increasing importance of immunochemical methods in residue analysis. Not all of them are commercially available. Available commercial IAs have been listed in e.g. Dankwardt et al.,\(^{(2)}\) Hennion and Barcelo,\(^{(3)}\) Knopp,\(^{(8)}\) but a lot of movement has been observed in environmental IA markets, leading to the disappearance of IA companies. At the moment IAs for environmental contaminants can be obtained for example from Strategic Diagnostics Inc. (Newark, DE, USA, sells former Ensys, Millipore and Ohmicron kits) and EnviroLogix (Westbrook, MA, USA).

5.1 Water

EIA have been used intensively for the determination of pesticides in surface and rainwater\(^{(56,60,69,211–217)}\) and groundwater.\(^{(60,69,214,218,219)}\) A substantial number of these studies were carried out for triazine herbicides.\(^{(56,60,211,212,214,216,218,219)}\) This illustrates the widespread occurrence of these herbicides in the aquatic environment. Many groups have used commercial test kits, which allow the investigation of samples without time-consuming Ab production. Thurman et al.,\(^{(60)}\) for example, used a Res-I-Mune kit (ImmunoSystems) for the investigation of triazines in surface and groundwater. The EIA was compared to GC/MS results obtained from samples that were extracted by SPE. Correlation coefficients between 0.91 and 0.95 were obtained after introducing cross-reactivity factors for each of the triazines in order to calculate a sum parameter for the GC. The majority of the samples contained only atrazine (up to 3 \(\mu\)g L\(^{-1}\)). Therefore, the EIA results corresponded well with the atrazine concentrations obtained by GC/MS.

Mouvet et al.\(^{(220)}\) compared four commercially available test kits and one in-house developed assay for the determination of triazines in surface and groundwater. Operational characteristics, cross-reactivity, sensitivity, CV and agreement with GC/LC (gas chromatography/liquid chromatography) measurements were investigated. DLs were determined between 0.003 and 0.07 \(\mu\)g L\(^{-1}\). Intra-assay CVs were below 7% for all tests, interassay CVs below 20%. Correlation studies between the EIA kits and GC/LC were carried out for samples from different water matrices. Depending on the water source, different levels of significance were observed with different tests. The best results were obtained for surface water, while not all kits showed a good agreement for lysimeter samples.

Apart from the triazines some other pesticides were investigated in water samples, also using commercial test kits. Alachlor was determined in ground and surface water using commercial tests.\(^{(213)}\) SPE was carried out prior to EIA to remove interfering substances and to concentrate the analyte. Concentrations of up to 0.8 \(\mu\)g L\(^{-1}\) were observed, and a comparison with GC/MS

showed a correlation coefficient of 0.95 with a slight underestimation by EIA. The occurrence of carbaryl was determined by Marco et al.\cite{221} in wellwater from Spain with their own assay and compared with a commercial test kit. Both IAs yielded a good agreement with conventional methods. Concentrations of 0.08–1.37 µg L$^{-1}$ were observed. Two commercial test kits were used in the Netherlands to determine 2,4-D concentrations in the rivers Rhine and Meuse.\cite{217} By diluting the kit standards with kit zero-buffer and calculating the DL on the basis of the error in the zero-standard, the DL as originally indicated by the manufacturer was significantly lowered. The water matrix substantially affected the recovery of 2,4-D with one assay kit, yielding unexpectedly low recoveries in demineralized and tap water. However, similar results were obtained by EIA and GC/MS for spiked samples from the river Rhine (with a slope of about 1 and $r = 0.99$). Routine samples were also analyzed.
and yielded analyte concentrations mostly below the DL (0.03–0.05 µg L⁻¹).

5.2 Soil

Many studies for pesticides in soil have been carried out for triazines. Other analytes include carbofuran, chlorpyrifos, hexazinone, metolachlor, 4-nitrophenol, PCP, and triasulfuron. Usually, the pesticides are extracted from soil with organic solvents such as acetone, ethyl acetate or methanol. In some cases, for example in the investigation of the quite water-soluble atrazine, extraction with water was sufficient. In one study no difference was observed in EIA measurements after extraction of atrazine from corn fields with water or acetone. Owing to the extraction with water it was very easy to apply the samples directly to the IA. However, in most cases the sensitivity of the assays is high enough to dilute organic solvent extracts sufficiently so that they do not interfere with the assay. The use of supercritical fluids for soil extraction is becoming increasingly popular. The low critical temperature (e.g. 31 °C for CO₂) means that low extraction temperatures can be used to recover thermally unstable solutes. Wong et al. compared SFE with solvent extraction using ethyl acetate for the investigation of parathion and 4-nitrophenol from soil. The extraction with water or acetone,.
Therefore 2–5 µg L\(^{-1}\) are considered the lowest cabaryl concentrations in juices that can be reliably measured with the EIA. CVs ranged from 4 to 13%, with most of them below 8%.

A dip-stick IA using mAb immobilized on a membrane was used for the determination of atrazine in water and liquid food samples.\(^{(46)}\) The measuring range was 0.3–10 µg L\(^{-1}\) using reflectance detection. The total assay time was 25 min using precoated dip sticks. The atrazine concentrations could be determined directly in spiked water, milk and juice samples yielding satisfactory agreement with the spiking concentrations. The black tea samples, however, showed an overestimation due to the unspecific binding of the tannins to the membrane.

Paraquat was determined in milk, beef and potatoes using an EIA with pAb.\(^{(233)}\) Potatoes were shredded with dry ice. The potato and the meat samples were extracted with HCl after spiking the samples. The acid extracts were evaporated to dryness and reconstituted for the EIA. The milk was diluted with phosphate buffer. The EIA was able to detect less than 1 ppb of paraquat in whole milk and down to 2.5 ppb in beef. The efficiency of HCl for extracting potato and ground beef was determined by using methyl-\(^{14}\)C paraquat. Recoveries between 60 and 70% were obtained. Since paraquat is known to bind tightly to many matrices, recoveries for both matrices were determined after storage of the spiked samples for several days at 21 °C.

Ibrahim et al.\(^{(233)}\) investigated eggs for aldrin and dieldrin residues. An EIA with pAb was applied. The EIA detected only dieldrin, but aldrin is metabolized to dieldrin. The eggs were homogenized after removal of the shell. This solution was diluted 1:2 with wash buffer containing 2% BSA. Egg samples were collected in Egypt and assayed by EIA. The standard curve for dieldrin was prepared in egg solution of noncontaminated eggs. The egg samples showed concentrations of aldrin and dieldrin in eggs up to 0.7 mg L\(^{-1}\). These are concentrations above the World Health Organisation average daily intake levels.

### 5.4 Biomonitoring

Human biomonitoring involves the measurement of a parent chemical and/or metabolites or a product of its reaction with cellular components (e.g. protein adduct, nucleic acid adduct) in selected tissues, body fluids such as blood, milk, urine or sweat, or expired breath of an exposed individual.\(^{(8,9)}\) Most IAs for pesticides are sensitive enough for biomonitoring. Many analytes could be determined without any sample preparation other than dilution with water or buffer. In some cases the sample was filtered. Slightly reduced sensitivity or higher blank values due to matrix effects were sometimes found when the assay was performed directly in the biological sample.

With increasing hydrophobicity of the analyte, sample preparation becomes more complicated.\(^{(8)}\)

Validation experiments are carried out by fortification of samples with the analyte in question and comparison with independent control methods such as GC, GC/MS or LC. Samples from a number of individuals should be used in any validation experiment because of the inherent variability of biological matrices. Features such as pH, protein, sugar and salt concentration must be considered. Also the intake of drugs can interfere with the immunological-determination of environmental pollutants.\(^{(8)}\)

While many investigations were restricted to spiked samples only, some studies demonstrated the use of IA for surveillance of occupationally exposed individuals (e.g. for DDA, a metabolite of DDT, 2,4-D, paraquat and atrazine mercapturate).\(^{(140,171,234,235)}\)

### 6 NEW DEVELOPMENTS

The strength of immunochemical methods lies in the screening of a large number of samples within a short time at low cost. Therefore, they can be valuable supplements to conventional analytical methods. Important applications are seen in the analysis of ground and drinking water, where matrix effects are seldom observed. Also, food commodities that turn over quickly are ideal targets for IA measurements. Owing to the low cost of one analysis more replicates from one site can be measured or special sites can be sampled more often, for example to obtain more information about variations of analyte concentrations depending on seasons or rainfall, etc.

Some restrictions are imposed by the fact that IAs are de facto single analyte methods. However, new approaches for multianalyte measurements are being undertaken, such as the integration of IA with LC. Here, Abs are used in conjunction with LC, e.g. to concentrate an analyte from a large volume of sample and separate it from an interfering matrix.\(^{(236–239)}\) In this case an immunoadsorbent column is used before analysis by LC. The immunoadsorbent column contains immobilized specific Abs which bind the analyte, while interfering substances pass through. The analyte can be eluted by using a pH gradient\(^{(79)}\) or an organic solvent.\(^{(80)}\)

Therefore, large sample volumes with low concentrations of the analyte can be reduced to small volumes with sufficiently high concentrations without coextracting interfering substances like HAs or food compounds. This raises the effective sensitivity of the analysis. Abs mixtures can be used to bind substances from different compound classes, e.g. the phenyl urea herbicides and the triazines.\(^{(239)}\) In this case, the eluted compounds were injected into the LC, yielding a DL of 0.03–0.5 µg L\(^{-1}\) from samples volumes as low as 25 or 50 mL.
When cross-reacting Abs are applied in IA, the signal obtained is not only related to the analyte, but also to similar compounds. This problem can be circumvented by the use of LC prior to the IA. LC/IA was applied by Krämer et al.\textsuperscript{(256)} to determine 4-nitrophenols. The nitrophenols were separated by different LC systems and determined by IA. LC/IA was about 8–10 times more sensitive compared with LC with ultraviolet detection. Therefore, the integration of LC with IA combines the high separation quality of LC and the sensitivity of IA.\textsuperscript{(240,241)}

Furthermore, multianalyte systems are under development. One concept is the microspot IA.\textsuperscript{(242)} which uses many microspots with fluorescence-labeled Abs of different selectivity immobilized on a chip. After incubation with the analyte (Ag or hapten) a fluorescence-labeled tracer Ab is added. The tracer Ab is either directed against the Ag or consists of an anti-idiotype Ab directed against the binding site of the capture Ab. Sensor and tracer Ab carry different fluorescence labels. Therefore it is possible to determine the amount of analyte bound to the sensor Abs with optical scanning methods by measuring the signal ratio (ratiometric assay). Lately, a variety of noncompetitive and competitive microspot analysis systems have been developed, mainly related to the medical field.\textsuperscript{(243)} but are clearly of particular importance in areas such as environmental monitoring.

Another possibility is the use of cross-reacting Abs for multianalyte detection. Known cross-reactivities of different Abs can be used to calculate the different concentrations of different analytes in a sample containing several contaminants.\textsuperscript{(244)} The estimation of the individual concentrations is carried out by complex calculating procedures, e.g. by neural networks\textsuperscript{(245)} or iterative procedures.\textsuperscript{(246)}

Immunochromimetric analysis is a fast developing field with numerous possibilities for further improvement. Much effort is being put into the development of continuous measurements, such as flow-injection immunoanalysis (FIIA) and immunosensors.\textsuperscript{(247,248)} A quasicontinuous FIIA of pesticides was developed by Krämer and Schmid\textsuperscript{(249)} on the basis of a competitive IA. Here, the Abs are immobilized on a membrane. The reaction takes place in the membrane reactor, the central part of the flow injection system. All reagents are sequentially added to the reactor and the product is assayed with the aid of a flow fluorimeter. The measuring range of the flow injection analysis almost equals that of the EIA. Wittmann and Schmid\textsuperscript{(250)} used an Ab column reactor filled with polystyrene or glass beads with the Ab immobilized via the avidin/biotin system. This system showed a stable Ab activity for a minimum of 500 measuring cycles. DLs for atrazine of about 1 ng L\textsuperscript{-1} with pAb and 30 ng L\textsuperscript{-1} with mAb could be reached.

Important progress is to be expected in the field of immunosensors where the detectors are based on Abs.\textsuperscript{(247)} Some relatively simple devices such as dip sticks and immunofiltration assays have been mentioned before (see section 3.3). An interesting development is liposome-amplified immunomigration strips.\textsuperscript{(251,252)} They employ liposome-encapsulated markers which act as signal enhancers of the competitive binding reaction instead of enzymes. These devices have been used for the determination of alachlor.\textsuperscript{(251)} If a pesticide of interest is conjugated to a lipid it can also be incorporated into the liposome structure, leading to a competitive liposome IA.\textsuperscript{(255)} In more complicated systems the immunological recognition system is immobilized in the direct vicinity of a transducer, an electrochemical, optical or gravimetric device. They respond to chemical compounds or ions and yield electrical signals which depend on the concentration of the analyte. Immunosensors with piezoelectric crystals as physical sensors are in a relatively advanced state of development.\textsuperscript{(254)} They function as microbalances onto which Abs are immobilized. Other physical sensors use optical systems such as surface plasmon resonance (SPR), interferometry or grating couplers.\textsuperscript{(248,255,256)} A biosensor employing SPR was used for the determination of atrazine.\textsuperscript{(256)} A DL of 0.05 µg L\textsuperscript{-1} for atrazine in water was reached with an analysis time of 15 min. Bier and Schmid\textsuperscript{(257)} used a grating coupler immunosensor for the determination of terbutryn, a triazine herbicide. A DL of 15 nmol L\textsuperscript{-1} (ca. 3.6 µg L\textsuperscript{-1}) was established. Interesting developments can be expected from Ab electrodes.\textsuperscript{(258)}

New strategies for Ab production are also being developed. Genetically engineered Abs appear very attractive because their selectivity and affinity can be tailored by site-directed mutations without requiring new immunizations.\textsuperscript{(259)} Methods are now provided to isolate desired clones rapidly from Ab libraries and to manipulate individual rAbs to match specific demands of environmental analysis. Binding proteins derived from Abs but consisting only of a part of their light or heavy chain (scFv, Figure 2) and rAb fragments, Fab, directed against different s-triazines, diuron and parathion have been produced.\textsuperscript{(260–264)} In several cases the DL of the rAb was the same as with the parent mAb.\textsuperscript{(263,264)}

A promising goal is the completely synthetic production of binding proteins or other synthetic receptors which are fitted to the structure of the analyte by molecular design. The use of libraries guarantees to close the bottleneck in Ab production. Abs with special properties such as resistance to matrix effects or organic solvent stability can also be selected from libraries, providing an important contribution to the analysis of water and food samples.
ACKNOWLEDGMENTS

I am grateful to Dr Armin Naß, Sension GmbH, Augsburg, for reading the manuscript and to Dr Sabine Pullen, Institute for Pharmacology and Toxicology, University of Erlangen, for providing some material on immunoassays for pesticides.

1 Introduction

1.1 Reasons for Analysis

Pesticides are essential in agriculture to meet the food supply demands of the world. However, owing to notable transgressions that have occurred related to the dangerous use of pesticides harmful to human and ecological health, many people throughout the world have grown fearful of pesticides. Real and perceived concerns about pesticides have led to their strict regulation, and the need for a variety of analytical strategies in diverse applications.

The analytical strategy that is used for multiclass, multiresidue analysis of pesticides depends, in part, on the need for the results. Analytical methods are needed to monitor pesticide residue levels in food and other sample types, to help measure toxicological or other effects of pesticides employed in the analytical strategy. Common matrices for pesticide analysis consist of solids, liquids, and gases in applications associated with food, agricultural, environmental, and other sample types. Varying degrees of pesticide–matrix interactions in different materials require more or less stringent extraction procedures to separate the pesticides from the sample. Sample preparation in multiclass, multiresidue strategies frequently utilizes liquid–solid, liquid–liquid and other partitioning processes including those, such as pressurized fluid extraction (PFE), in which pressure and temperature of different fluids are controlled. Extracts often require cleanup to remove interfering co-extracted matrix components prior to analysis. A variety of cleanup techniques based on a number of partitioning processes, such as liquid chromatography (LC), may be employed in an on-line or off-line fashion. Lastly, the sample extract is usually further separated and analyzed using one or more techniques. The majority of pesticides are analyzed by gas chromatography (GC) with mass spectrometry (MS) and/or element-selective GC detectors. High-performance liquid chromatography (HPLC) is often used in the analysis of thermally labile pesticides that are not amenable to GC analysis. Other alternatives for analysis of certain pesticides include capillary electrophoresis (CE) and immunoassays. Fundamentally, a high degree of selectivity helps in generating excellent analytical results, but the wide polarity range of analytes in multiclass, multiresidue methods (MRMs) for pesticides necessitates a great deal of effort to attain a high degree of selectivity. Trade-offs and compromises are omnipresent in multiclass, multiresidue analysis of pesticides, and a host of strategies are available depending on how the analytical chemist prioritizes the analytical and practical considerations.
the pesticides on living organisms, and to discover the fate and transport of pesticides in plants, animals, and the environment. For quantitative risk assessment purposes, it is necessary to identify and quantify accurately a great number of pesticide residues at low levels (e.g. less than nanograms per gram). In other situations, it may only be necessary to screen rapidly for certain pesticides of concern at higher levels. Also, practical considerations, such as time, labor, instrumentation, and budget, although not formal analytical figures of merit, are frequently limiting factors in the type of approach chosen by a laboratory.

Many situations in the modern world require the screening, quantitation, and/or identification of pesticide residues in food, the environment, and other types of samples. Even before a potential pesticide product is developed and introduced into the market, manufacturers must have the means to isolate, analyze, and characterize the chemical in order to gain an understanding of its nature and effects. If the manufacturer decides to introduce the pesticide into the market, nearly all nations require that the pesticide be approved (or registered) for specified uses in their country or group of countries. One common facet of the pesticide registration process requires that acceptable analytical methods be available, or that new methods be developed, for the parent pesticide and potentially harmful transformation products or coformulants.

Pesticide manufacturers are usually required to test the utility of common MRMs when applying for registration of a new pesticide. In the USA, the MRMs for foods are published in the Pesticide Analytical Manual, Vol. I (PAM I). However, for a new pesticide, the PAM I MRMs may fail to achieve adequate recovery (typically >70%) or detection limit (less than half of the regulatory limit) for reasons related to the nature of the pesticide, matrices of interest, the need to detect metabolites, and/or an inability to modify the PAM I methods. In this case, the manufacturer must develop a new method, which will likely be a single analyte method specific to the pesticide and commodity of interest. In the USA, these methods are published in the Pesticide Analytical Manual, Vol. II (PAM II). Modification of a multiclass, MRM or the development of a new method to widen the analytical range may be possible, but the manufacturer has little incentive to develop such an approach which could take much time and effort, benefit its competitors, and lead to greater enforcement monitoring of the product once it reaches the market. In general, single analyte methods in PAM II are complicated, rapidly outdated, and infrequently used in monitoring of pesticide residues owing to the cost of conducting many separate analyses. However, the use of multiclass, MRMs usually provides the most efficient approach for pesticide analyses.

Individual governments and international bodies, such as the Codex Alimentarius, commonly set maximum residue limits (MRLs), which are known as tolerance levels in the USA, for pesticides in food commodities and other matrices, such as water, which may be exposed to pesticides. Proper usage of pesticides is enforced, in part, by periodic monitoring of pesticide residues in collected samples. Nearly all governments worldwide (national and often local) conduct multiresidue pesticide analysis for food and other matrix types. A stipulation in international trade is that imported foods must not contain violative levels of pesticide residues. Thus, food imports are often tested at a higher sampling rate than domestic products, as included in Table 1. Furthermore, it is not unusual for

pesticide or other types of residues to be used as a trade barrier or hurdle to help protect domestic markets.

Many industrial and academic purposes also necessitate the analysis of pesticides. For example, food processors, or their contract laboratories, often perform testing to ensure that pesticides do not occur in their products at adulterating amounts. Toxicologists, ecologists, agricultural and environmental scientists, and several others also require the multiclass, multiresidue analysis of pesticides in many types of studies. Individuals, consumer groups, and environmental organizations may also hire contract laboratories to analyze pesticides in various types of samples for a number of reasons. Additionally, the continuing rapid progress being made in analytical instrumentation and techniques have led to a great deal of method development and evaluation studies which involve the analysis of a large number of samples. Analytical methods approved by the US Environmental Protection Agency (EPA) for pesticides and other contaminants in environmental samples have been published.\(^3\)

Estimation of the number of multiclass, multiresidue analyses of pesticides that are performed yearly around the world is difficult. Essentially, only analyses performed by government agencies in their food monitoring and compliance programs are published, and Table 1 lists the number of analyses reported by selected countries. Many more samples are analyzed than those presented in Table 1, and it is safe to estimate that >150,000 multiresidue pesticide analyses are performed by governments and industry yearly worldwide.\(^4\)

### 1.2 Matrices

A variety of matrices are regularly analyzed for pesticide residues. These matrices can be broadly divided into “environmental” and “food and agricultural” sample types. Environmental samples can be divided into air, water, and solids (soils, sediments, particles, sludges, nonanimal solid wastes, and surfaces). Plant, animal, and fungi samples, including bodily fluids, may be taken for clinical, environmental, or other purposes, but owing to their similar compositions as some foods, they will be classified as “food and agricultural” samples. Therefore, “food and agricultural” items essentially consist of all edible and nonedible organisms, tissues, and products from organisms. Examples include fruits, vegetables, grains, nuts, beans, fish, meats, meat byproducts, eggs, poultry, animal feed, dairy products, beverages, spices, honey, mushrooms, processed foods, dried fruits, tobacco, plant tissues, bodily fluids, animal waste, and a host of other materials (drinking water will be regarded as an environmental water sample rather than a beverage). For purposes of residue analysis, food and agricultural matrices can generally be divided based on their composition, particularly with regard to water and fat content.

#### 1.2.1 Food and Agricultural Samples

Because agricultural applications make up the largest area of use for pesticides, and food safety is such an important concern, foods are a widely analyzed matrix type for pesticide residues. Raw commodities, such as fruits and vegetables, are often the most appropriate food items in which to monitor pesticides because they are generally ready for consumption nearest to the times of pesticide applications and typically have the highest residue concentrations.

Foods are often complex matrices with widely varying compositions, but many foods consist of four major components: carbohydrate, fat, protein, and moisture. A fifth component, ash (or mineral composition), is rarely >5%. Of the four major components, carbohydrates include sugars, starches, oligosaccharides, and fibers; fat includes mono-, di-, and triglycerides, oils, fatty acids, and sterols; protein includes all organonitrogen components (amino acids, enzymes, etc.), and moisture is essentially water content.\(^5\) For nutritional labeling purposes and simplicity, food chemists have deleted water from consideration and developed a diagram, as shown in Figure 1, to help categorize foods based on the relative compositions of proteins, lipids, and carbohydrates.\(^6\) Figure 1 contains nine smaller equilateral triangles to serve as representational sectors in which similar food types appear (some examples of the relative compositions of different foods are provided in the diagram). USDA provides a Nutrient Database that is accessible in searchable format on the internet and currently lists the compositions of about 6000 food items.\(^7\)

![Figure 1 Major composition of foods. [Reprinted from Wolf.\(^8\)](image-url)
The capability of analytical methods can be matrix dependent, but the great variety of foods limits practicality to validate new analytical methods for all food matrices. For this reason, scientists within the Association of Official Analytical Chemists (AOAC®) International have proposed that one type of food within a sector could serve as a reference for other types of foods within the same sector, particularly for methods to measure food composition. For example, investigators in one study involving nonfatty foods chose 27 pesticides in six matrices (apple, carrot, spinach, strawberry, tomato, and wheat) to represent the broader scope of pesticides and commodities in a comparison of different multiclass, MRMs of analysis among 24 laboratories.

For residue analysis and other purposes, the FDA has categorized and coded many different food products, which are summarized in PAM 1. Table 2 provides ranges of % fat, % water, and % sugars of selected commodities. In broader terms, the FDA separates analytical methods that are applicable to fatty (>2%) and nonfatty (<2% fat) foods. Further demarcations can be drawn based on % water or % sugars, but it is easy (and sometimes necessary) to add water or sugars to the matrix during sample preparation, whereas fats are never added. There are instances when the addition of sugar helps in a liquid–liquid partitioning step, and the presence of water in an analytical procedure can be a critical benefit or detriment depending on the application. Thus, rather than devising a number of different strategies depending on the matrix, it is possible to limit the number of necessary methods by forcing the matrix to suit the method. Similarly, some analytical methods may include procedures, such as gel permeation chromatography (GPC), that are able to remove fats from sample extracts even though the samples may not contain fat. This concept is not necessarily the most efficient, but it does limit the number of different methods needed in the overall strategy for diverse matrices.

Fatty foods are known for their greater difficulty in analysis owing to smaller differences in the polarity of lipids from many common pesticides. Furthermore, greater importance is often placed on the analysis of lipophilic pesticides, such as organochlorines, in fatty foods because those pesticides may be persistent, bioaccumulative, and/or pose higher human health or ecological risk. Nonlipophilic pesticides do not accumulate in animal tissues, hence there is less need to monitor for them in fatty matrices.

Nonfood plant and animal tissues can often be treated in a similar fashion to food items based on their composition; however, the nutrient compositions of tissues inedible to humans are not as well documented. Also, the cell walls and exoskeletons of plants and animals not generally eaten by humans often require more effort to rupture during extraction than the techniques used for food items. For example, longer extraction times, acid–base conditions, and/or higher temperatures may be needed. Furthermore, more complications in analysis can occur owing to the potential interference of natural compounds developed in defense and other evolutionary processes. For these reasons, in part, it is common for analysts to devise single analyte or single class residue methods for unique matrices. In some matrices, it may be impossible to achieve sufficiently low detection limits and high recoveries for a wide polarity range of pesticides with traditional multiclass, MRMs.

**1.2.2 Environmental Samples**

**1.2.2.1 Water** Environmental water samples consist of drinking water, surface and groundwater (salty or fresh), precipitation, ice, process streams, waste effluents, and other aqueous media. Water is generally considered an easy matrix for pesticide residue analysis because it often contains few interferences and is usually sampled as a homogeneous liquid. Water samples are often filtered to remove suspended particles which allows the separate determination of dissolved analytes from those associated with the particle phase. Very low detection limits can be achieved by concentrating extracts from large sample volumes. However, some water samples with high concentrations of organic substances, such as marsh water or waste streams, may require cleanup of the extracts. Solid-phase extraction (SPE) has become the primary means to extract and cleanup water samples.

**1.2.2.2 Solids** Soils, sediments, sludges, compost, particles separated from water and air, surfaces, and other solid environmental materials can be categorized as environmental solid sample types. Sediment is essentially
the same as soil except that it occurs underwater; sludge is the waste material that settles in waste treatment plants or other facilities. Soils and other environmental solids tend to have much stronger adhesion and/or other forms of chemical interactions than other types of matrices. An unsettled issue among pesticide residue chemists is whether special measures should be taken to extract bound residues that are covalently or otherwise strongly infused with the matrix.\(^\text{(11)}\) In the pesticide registration process in the USA, the EPA requires that a \(^{14}\)C-labeled analyte be used in method development studies to determine the total extractability of the pesticide in the targeted matrices. In the case of soils, the extraction process of pesticides often requires stronger measures (sonication, longer extraction times, acid–base conditions, repetitive steps, and/or higher temperatures) than in the case of food samples.

The variability of soils is very high, and just as nutritionists have characterized foods by protein, carbohydrate, and fat (Figure 1), soil scientists have developed a textural classification diagram for soils based on sand, silt, and clay content (Figure 2). The classification boundaries and nomenclature of soil types appear in the diagram (loam is a mixture of sand, silt, and/or clay). According to USDA definitions, sand (and gradations thereof) has particle sizes between 0.05 and 2 mm, silt particle sizes are between 0.002 and 0.05 mm, and clay consists of particles smaller than 0.002 mm.\(^\text{(12)}\) Sand separates (very fine, fine, medium, coarse, and very coarse) are determined by sieving, and silt and clay are differentiated by their settling rates in water. Particles larger than 2 mm, which have little bearing on either soil properties or analytical residue methods, are considered as stones or gravel and are excluded from the textural classification.\(^\text{(12)}\)

As in the case of the food classification diagram, water is not represented in the soil textural diagram even though it can be a major constituent. The organic content of soils, which can be likened to the many potential analytical interferents in food and agricultural samples, is also an important component that is left out of the diagram (the organic content is usually a low percentage overall). However, water, salts, pH, and organic content can all have major effects in the analysis of pesticides in soils, sediment, sludges, compost, and suspended particles.

Other types of solid samples that may be analyzed for multiple types of pesticides include exposed surfaces. Flooring, counters, and other surfaces may be sampled by rinsing or wiping with solvents to test for effectiveness and legality of pest control in homes and businesses, and clothing, skin, hair, and similar materials may be sampled in the study of occupational or other cause of exposure to pesticides. Also, it is sometimes necessary to test container surfaces to determine unknown types of pesticides that may have been present previously or to study the effectiveness of a cleaning process. Similarly, multiclass, MRMs are needed to identify unlabeled pesticide formulations or waste materials of unknown origin.

### 1.2.2.3 Air

Owing to the nature of the gaseous medium, air samples require very different approaches, particularly in the sample collection process, to those employed for solids and liquids.\(^\text{(13)}\) Sample volumes are determined by flow rates, time, temperature, and pressure, which must be known to convert volumes to standard conditions. Collection of fog and suspended particles in air also requires unique procedures, but once air or samples from the air have been collected, cleanup steps are rarely required. Typically, the sample extracts are concentrated in a liquid or solid-phase trap and injected directly into a GC column for analysis. LC is generally not used owing to the nature of typical pesticide analytes found in air and more complicated injection procedures for air samples. Constituents from very high volumes of air can be concentrated by trapping to achieve exceptionally low detection limits (below the nanograms per cubic meter level).

### 1.3 Pesticides

The diverse range of purposes and sample types for pesticide analysis is only matched by the diversity of chemicals to be analyzed. There are numerous sources of information on the chemistry, applications, and regulation of pesticides.\(^\text{(14–17)}\) A brief review of fundamental aspects of pesticides is provided in the following paragraphs.
The term “pesticide”, as defined by the EPA, broadly represents “any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest”. These pests can be divided into categories such as weeds, insects, arachnids (mites and ticks), fungi, slugs, nematodes (a type of worm), rodents, microorganisms, and miscellaneous other pests, which form the basis for the more specific terms, “herbicides”, “insecticides”, “acaricides” (or “miticides”), “fungicides”, “molluscicides”, “nematicides”, “rodenticides”, and “antimicrobial pesticides” (and “biocides” or “disinfectants”). Pesticides also generally include fumigants, sterilants, growth regulators, defoliants, repellents, and synergists (compounds that aid action of a pesticide). For the purpose of simplicity, the term “insecticide” is commonly used to include all pesticides used for control of animal pests, “herbicide” includes plant growth regulators, and “fungicide” can also refer to chemicals used in noninsecticidal postharvest applications (e.g. antiscalding).

In strict terminology, broader or narrower terms have been devised, such as “agrochemical” (to include fertilizers and other compounds of agricultural significance), or “crop protection agent” (to differentiate agricultural and nonagricultural uses of pesticides), but sometimes other terms, such as “plant protection product”, are used to avoid the word “pesticide” for public perception reasons. Pesticides also include natural chemicals used for pest control, but these are sometimes called “alternative” or “natural” pesticides to distinguish them from synthetically derived pesticides.

Agricultural usage of pesticides constitutes the largest application sector, but home, business, and other pest control applications are also significant. The USDA National Agricultural Statistics Service (NASS) provides annual reports, which are accessible through the Internet, concerning pesticide usage on field crops in the USA. Concerning pesticide usage on field crops in the USA. Annual reports, which are accessible through the Internet, provide the National Agricultural Statistics Service (NASS) provides a basis for the more specific terms. “Herbicides”, “insecticides”, “acaricides” (or “miticides”), “fungicides”, “molluscicides”, “nematicides”, “rodenticides”, and “antimicrobial pesticides” (and “biocides” or “disinfectants”). The USDA National Agricultural Statistics Service (NASS) provides annual reports, which are accessible through the Internet, concerning pesticide usage on field crops in the USA. A few approaches, such as atomic emission detection (AED) after GC, may be able to analyze organometallic species in the same procedure as other classes of pesticides, but it is more common to have separate methods for organometallics.

1.3.1 Herbicides

Table 3 presents major classes of herbicides, their solubility range in water, common examples of individual herbicides within each class, and their basic chemical structures. Many herbicides are applied early in the agricultural season and generally dissipate rapidly. Furthermore, more recently introduced herbicides, such as sulfonylureas and imidazolinones, tend to have selective weed-control properties, pose little toxicological threat to animals, have relatively low application rates, and degrade rapidly. Few herbicides appear as residues in foods, and many are not commonly included in multiresidue, multiclass methods. Those which have longer environmental persistence than a few months, such as some triazines and acetamides, can typically be recovered and detected at low levels (nanograms per gram) using many current multiclass, MRMs, and are frequently included in analyses, but they are still rarely found in foods. Herbicides, such as triazines, are frequently found in environmental water and soil/sediment samples. Owing to the relatively high polarity and often ionic nature of many herbicides, they are more prevalent in water and soil samples than in food and air matrices. Owing to the nature of the analytes, the development of multiclass, MRMs for polar/ionic herbicides is more difficult than in the case of less polar pesticides. Instrumental approaches, such as HPLC or CE, may permit the simultaneous analysis of multiple polar/ionic herbicides, but few cleanup techniques allow the recovery of a wide range of polar analytes in complex matrices. Hence, typical multiclass, MRMs for polar herbicides are generally only useful for relatively clean aqueous matrices.

1.3.2 Insecticides

Many insecticides are also used as acaricides, nematicides, and rodenticides, and vice versa. A few herbicides (dinitrophenols) and fungicides (organotins) may also have insecticidal activity, and the categorization of pesticides can depend as much on how a pesticide is used as its chemical class. Table 4 lists the major classes of insecticides on the basis of relatively similar chemical structures. In some classification schemes, the elemental composition of the pesticide determines its category, such as organophosphorus, organonitrogen, organosulfur, and

organochlorine (or organohalogen). This classification approach is useful when considering which type of elemental selective detector in GC can be used, but the pesticides within these categorizations are not necessarily recovered through the same extraction and cleanup approaches. Also, there is considerable overlap for many pesticides that contain more than one of these elements. Both of these circumstances are also true for chemical structural classification schemes, but there is less overlap.

Chlorinated hydrocarbon and cyclodiene insecticides, widely known as organochlorine pesticides (OCs), are the most widely analyzed pesticides in the most matrix types. They are most commonly detected in fatty and nonfatty foods, soils/sediment, water, and animal and plant tissue samples. Nearly all OCs were banned in industrialized nations during the 1970s, and essentially only endosulfan and dichloro, which are less persistent and pose less risk than the others, are still commonly used in these countries today. However, many of the banned OCs are still applied in several developing countries to combat malaria and other insect-borne diseases. In environmental and epidemiological studies, analytical methods often target OC insecticides along with polychlorinated biphenyls, polycyclic aromatic hydrocarbons, and other nonpolar contaminants in a similar or the same general approach.

Organophosphorus insecticides (OPs) are currently the most widely used insecticides, but they are less frequently monitored in environmental samples than the OCs owing to their lower persistence. In nonfatty foods, OPs are detected more frequently than OCs, and their residue concentrations are typically slightly higher, whereas the opposite is true in the case of fatty foods. The variety of OPs and their different uses are unmatched among all pesticide classes.

Carbamate insecticides, which are sometimes called N-methylcarbamates to distinguish them from (thio/phenyl) carbamate herbicides and (dithio)carbamate fungicides, are also frequently used in agricultural and home applications, but there are fewer carbamate insecticides than OPs. A few of the thermally stable carbamates (propoxur, carbofuran, and carbaryl) can be analyzed by GC methods, but a separate HPLC procedure is more commonly conducted for the simultaneous analysis of N-methylcarbamates. HPLC can also be used for the simultaneous analysis of OPs along with carbamates and other pesticides, but capillary GC provides superior separations and more sensitive detectors for the numerous OPs. The use of single class, or selective, MRM's such as methods for carbamates, benzimidazole fungicides, phenylurea herbicides, and others are often incorporated into an overall multiclass, multiresidue strategy.\(^1,22\)

Owing to recent studies on neurotoxic effects of cholinesterase-inhibiting insecticides (OPs and carbamates), especially with respect to infants and children, there is currently much discussion among scientists, environmental groups, farmers, the chemical industry, regulators, and politicians about whether the use of OPs should be curtailed. For this reason, regulatory and risk assessment needs have further emphasized the detection of OP and carbamate pesticides at ultratrace levels in all matrices to which humans are exposed.

Pyrethroid, nicotinyl, alkyloid, and rotenone insecticides are either synthetically derived from naturally occurring compounds produced by plants in defense from pests or isolated from organisms themselves. The pyrethroids constitute the most widely used of these classes currently, and their use is expected to grow if the prevalence of OPs decreases. The human health risk of pyrethroid pesticides is lower than that of OPs but they commonly have higher acute toxicity to fish and other aquatic species. In the future, several other chemical, physical, and biological pesticide alternatives may help to reduce the reliance on many of the current commonly used insecticides.

### 1.3.3 Fungicides

Table 5 lists common fungicide classes and their basic structures. Some fungicides are used in preharvest applications to control fungi in the soil or above ground on plants. Other fungicides are used in postharvest applications to improve product quality or extend shelf-life. The fungicides that are used in postharvest applications are the most commonly found in fresh produce, and their concentrations can be much greater than those of other residues.\(^21\) Therefore, multiclass, multiresidue strategies for foods often include several fungicides in the approach, but several organonitrogen fungicides (azoles, imides, etc.) can be problematic in the procedures. However, there is little toxicological risk of approved postharvest fungicides to animals. Tolerances or MRLs for several postharvest fungicides are >5 mg kg\(^{-1}\) in fresh commodities, which can be more than 100-fold higher than some higher risk insecticides.\(^21\)

Postharvest fungicides are rarely expected to occur in environmental samples, and few environmental methods look for them. However, some preharvest fungicides may be found both in the environment and in foods. OC fungicides, such as chlorothalonil and quintozene, and transformation products are sometimes also included in multiresidue, multiclass analyses of environmental samples.

The widely used dithiocarbamate fungicides are not analyzed with the same methods as other pesticides owing to their chemical instability and unique properties.
A common strategy is to digest the dithiocarbamates to form either ethylenethiourea (ETU) or CS₂ for detection. The result represents a summation of all dithiocarbamates, but the chance of inaccurate results is substantial owing to natural sources of compounds that also produce ETU or CS₂ in the approach. Extraction with a basic buffer and ethylenediaminetetraacetic acid (EDTA) followed by ion-pairing HPLC can determine individual dithiocarbamates.

### 1.3.4 Pesticide Properties

In any analysis, the physicochemical properties of the analyte(s) determine the type of possible approaches that lead to a successful extraction, cleanup and detection procedure. An important aspect is the polarity of the analyte, which can be estimated for the purposes of this article through its solubility in water and/or its octanol–water partition coefficient (K<sub>ow</sub>). In the analysis of pesticides that are weak acids and bases, pH and ionic strength also become critical aspects in the approach. Other factors of note include volatility and stability, which indicate what precautions must be made to avoid analyte losses.

Several chemical properties of interest for many pesticides are listed in the USDA Pesticide Properties Database, which is also accessible on the Internet (http://www.arsusda.gov/rsml/ppdb.html). Figure 3 includes the 353 pesticides in the database categorized by their solubilities in water which broadly indicate the number of pesticides with a particular polarity range. Tables 3–5 provide the water solubility ranges of the different pesticide classes listed in the database. The majority of pesticides are considered to be semipolar, with solubilities in water of ~1–10 mg L<sup>-1</sup>, as can be seen by the profile in Figure 3, but many pesticides, generally herbicides, tend to be rather polar with solubilities in water >100 mg L<sup>-1</sup>. Polar pesticides are typically more problematic in multiresidue analysis, but they also tend to be less toxic to humans and less persistent in the environment. However, analytical strategies for less polar pesticides are fairly straightforward. The inclusion of polar pesticides increases the difficulty in the analysis and, in practice, it is more common to have separate methods for the most polar pesticides owing to their more unique characteristics. Even polar pesticides with the same solubility in water at a given pH may behave much differently in a particular approach owing to different functional groups, which is a less frequent problem for nonpolar and semipolar pesticides.

### 1.4 Quality Assurance and Quality Control

QA and QC overviews have been published. For pesticide residue monitoring of foods, a working group of the European Union (EU) recently published their recommended QA/QC guidelines. QA is the process to help ensure the quality of results using any analytical

1.4.1 Method Validation
Analytical methods must be validated through repetitive recovery studies of fortified samples and, depending on customer requirements and analytical needs, these studies may need to be performed in a minimum number of different laboratories. In the case of pesticide residue analysis, pesticide recoveries of 70–120% in matrix spikes using three replicates each at 2–3 different concentrations are generally acceptable. Depending on the concentration, the variability of the recoveries should be <20% relative standard deviation (RSD). Furthermore, methods must be capable of attaining the desired limit of quantitation (LOQ) which may be checked by spiking samples at this level. Some organizations require laboratories to submit only those results that have been obtained using prescribed methods that have undergone interlaboratory method validations.

The AOAC® International is an organization that is involved in the certification of analytical methods through interlaboratory collaborative studies in the analysis of shared samples. For a method to obtain AOAC® Official Methods or Peer Verified status, defined procedures are followed and certain statistical criteria for the results must be met. Interlaboratory validations for any method can be time consuming, laborious, and expensive, and subsequently a good method may still give inconclusive results in the study for a variety of reasons. The effort required to carry out a multiclass, multiresidue collaborative study is substantial, and to consider all analytes and matrices is practically impossible. Since 1980, only a single multiclass, MRM for pesticide residues in foods has been evaluated and attained Official Method status. The collaborative study, conducted in 1984, involved only six pesticides in three fruit and vegetable matrices. Another collaborative study was attempted only recently and the results were acceptable for nearly all of the 13 fortified pesticides evaluated in 3 commodities.

The rigorous requirements and great effort to perform interlaboratory validations have tended to stifle the implementation of new approaches for official monitoring purposes. It often takes many years for a new, advantageous technique to achieve general use, in part owing to stringent, impractical, or incompatible method acceptability parameters. For this and other reasons, the concept of performance-based measurement systems (PBMS) is common for multiclass, MRMs. PBMS relies on internal laboratory method validation results and QA/QC protocols to verify that the quality of analytical results is satisfactory. The proliferation in the use of proficiency testing, or blind check samples, has made it possible to determine the quality of results from a laboratory, analyst, and/or method in a situation reasonably close to real-world analysis. In some laboratories, check samples are prepared regularly by the QA officer, and more widespread programs have developed among a group of laboratories or in a fee-based service.

The proficiency test samples may contain naturally incurred residues in addition to those spiked into the matrix. One of the problems with the use of only spiked samples in method validation is that the pesticides are not incorporated as strongly into the matrix, so higher recoveries may be achieved for the spiked samples than real-world samples. However, results from studies involving the analyses of proficiency test samples indicate that several different methods can achieve equally valid results for many pesticides in food matrices.

The lack of a known concentration for incurred residues has made the determination of accuracy somewhat questionable, but comparison of results using different methods is useful. Standard reference materials are available for certain OCs in animal tissues or environmental solids to help verify analytical methods, but none have been developed for other types of pesticides. An attempt to develop a reference material for pesticides in grain determined that inadequate stability of the pesticides,
inhomogeneity of the samples, and variability in the results made the attempt unsuccessful.\textsuperscript{43} The comparison of results for shared samples has become a means by which new methods are commonly validated.

### 1.5 Strategies

Usually, the most efficient overall analytical strategy for a laboratory to reduce time, labor, and cost is to use the fewest possible methods for the most analytes. An inherent difficulty with multiclass, MRMs is that as the polarity range of analytes increases, more matrix co-extractives and potential interferences occur. No current method can analyze for all pesticides from all matrices with a single approach. Therefore, the overall analytical strategy depends on how the chemist decides to compartmentalize the range of analytes and matrices to be analyzed. The strategy is constrained by the laboratory budget/resources, among other factors, but it must still meet the QA criteria determined by the need for the data.

The majority of nonpolar and semipolar pesticides do not pose much trouble in analysis, and many techniques can achieve high-quality results for stable OCs, OPs, and similar compounds. The challenges and main differences in approaches occur for those problematic pesticides that are more volatile than the others, tend to degrade, possess matrix-dependent interactions, interfere in the detection of another pesticide, or stick to glassware, among other possibilities. For best results with problematic pesticides, single-analyte or single-class methods may be more appropriate.\textsuperscript{1,27,44} but this is not commonly possible in laboratories owing to the added effort and cost. The multiclass, multiresidue strategy within a laboratory should be developed to minimize cost and maximize convenience for the pesticides and matrices of interest while still meeting the needs for the results.

Figure 4 illustrates the monitoring strategy used by laboratories of the General Inspectorate for Health Protection in The Netherlands for the analysis of pesticide residues in fruits and vegetables. The “Dutch approach” is probably the most streamlined and cost-effective strategy implemented for a wide range of pesticide residues in fruits and vegetables, and it has been extensively evaluated.\textsuperscript{27}

However, the multiclass, multiresidue analysis of pesticides is a constantly evolving process. New pesticides, instruments, and techniques are frequently introduced, and continually changing priorities, budgets, and analytical needs compound the problem. Many chemists in many monitoring laboratories around the world are striving to devise the optimal approach. Even well-established methods are modified frequently, and few laboratories follow methods exactly as published in the literature, even those in which the published methods were originally developed.

---

**Figure 4** Current overall strategy of the Dutch multiclass, multiresidue analysis of pesticides in foods. HPLC methods: 1, \textit{N}-methylanilamides; 2, benzimidazole fungicides; 3, phenylurea herbicides; 4, benzoylphenylurea insecticides; 5, conazole fungicides. ITD, ion-trap detector. [Reprinted from A. de Kok, M. Hiemstra, presentation at the 2nd European Pesticide Residue Workshop, Almería, Spain, May 24–27, 1998.]

For example, Milton Luke of the FDA, the originator of the “Luke” method,\textsuperscript{45} has spent many years altering and optimizing the method named after him. In another case, Fillion et al. altered their primary multiclass, MRM used in the Canadian Monitoring Program in order to utilize new SPE cartridges in the market.\textsuperscript{46} Furthermore, the chemists in the Inspectorate of Health in The Netherlands took much time and effort to validate their current suite of methods as part of their overall analytical strategy, and they will likely spend several years in the future developing and validating new methods that take advantage of the improvements offered by recent advances in liquid chromatography/mass spectrometry (LC/MS) and other technologies.

Invariably, trade-offs and compromises are required in any multiclass, multiresidue strategy, and not all analytes will be recovered completely for detection at low levels in all matrices. Each approach may possess advantages and disadvantages with respect to certain pesticides, matrices, and practical aspects (convenience, costs, time, space, etc.). There are so many different variations in the analysis of pesticide residues that it is practically impossible to present them all. Thus, only major differences in the analytical process (sample preparation, analytical separations, and detection) will be presented in this article. Recent review articles for pesticide residue analysis can be found in a number of publications.\textsuperscript{47–50} Table 6 lists and compares different methods of analysis.

CDFA, California Department of Food and Agriculture; Current FDA, CDFA, and Canadian methods have been modified slightly from publications. SFE, supercritical fluid extraction; ODS, octadecylsilane; QMA, quaternary methylamine.

<sup>a</sup>  Costs vary depending on vendors; other costs not presented include labor, instrumentation, and indirect charges.
for multiple pesticide residues fruits and vegetables. Minor modifications of these methods (except in the case of the SFE method) often permit the analysis of fatty foods, and these methods are often also applicable to other matrices. Analytical methods commonly used for water, soil, sludge, and other environmental matrices have been published.(34,35)

2 SAMPLE PREPARATION

All aspects in the analytical process are equally important, and no step can improve upon the quality of the previous step in the procedure. A selective, sensitive, and rugged detection system can ease or reduce the sample preparation procedures in a method, but not improve recoveries. Unfortunately, a highly sophisticated detection system cannot improve upon poor sample preparation procedures, nor can the achievement of very accurate and precise results by a laboratory extend beyond the scope of what the samples collected statistically represent. Therefore, the analytical strategy actually begins with devising an adequate statistically representative sample collection scheme, proper sample handling protocols, and appropriate QA/QC guidelines to meet the goals of the analysis. The USDA Pesticide Data Program serves as an example what is required to plan and implement a monitoring program to meet specified needs.(21)

Sample preparation consists of homogenization, extraction, and cleanup steps. In the case of multiclass, multiresidue pesticide analysis, different approaches can have substantially different sample preparation procedures, but employ the same determinative steps. Some detection methods may permit fewer sample preparation steps, but in some cases the quality of the results or ruggedness of the method suffers when short cuts are attempted. The manner in which sample preparation steps overcome the selectivity vs. polarity range conundrum inherent to multiclass, multiresidue analysis is often the most pivotal facet in the overall approach.

2.1 Homogenization and Sample Size

The choice of sample size and homogenization step begins the analytical strategy in the laboratory. However, sample collection, transport, and storage begin the overall process and as much care must be taken in these steps as any other. In applications that require the most care in the analysis, samples should be stored frozen, generally at the temperature of dry ice sublimation (−78.5 °C), or at −40 or −20 °C in freezers. For water samples, which may be too large to store in most laboratories, extraction is often performed as soon as possible after collection, and the concentrated extracts are stored. In many pesticide monitoring applications, even extremely large samples are extremely small in comparison with the commodity, environmental area, or other unit that the sample is meant to represent. It is often better to take several replicate samples of a manageable size, depending on the situation, rather than a larger sample that may be difficult to homogenize. The degree of variability of the sample type is determined by taking samples from different locations at the same time and/or samples at the same location over the course of time.(55)

Sample sizes in environmental applications generally range from very small (<1 g in particle phase samples) to very large (e.g. 400 m³) in air analysis. For water, sample size is typically 1–4 L, but smaller or larger samples are sometimes adequate or necessary in certain applications. Soil samples range from ca. 3 to 100 g but, unlike many food samples, homogenization and subsampling procedures with large samples are not generally performed. Replicate samples from the monitoring area to be assessed are usually analyzed instead to improve the accuracy of the overall results.

In fresh food commodity applications, the FDA recommends taking samples of at least 20 lb. (9.1 kg) for comminution using an appropriate chopper.(1) However, many food sampling programs commonly take smaller sample sizes. In some cases, the variability of the individual items of the commodity is a goal of the study which involves the analysis of many individual items. Furthermore, the distribution of the pesticides within a single item may be desired, and appropriate samples (exposed surfaces, inner tissues, different sides, etc.) may be taken.

For extraction, current approaches do not conveniently extract solid samples sizes greater than 100 g, nor would larger sample sizes be desirable in most applications. Hence, subsampling of the larger composite sample is generally needed prior to extraction, and it is very important to homogenize the composite sample as well as possible. Miniaturization of the subsample size taken for analysis generally leads to a more cost-effective and convenient approach, and smaller amounts of potentially interfering matrix co-extractives have to be contended with or removed. In general, the smallest sample size should be taken that adequately represents what is intended and allows an adequate LOD. Increasing the sample size does not decrease the LOD if matrix co-extractives are the limiting source of noise in the analysis.

Simple precautions taken during the homogenization step can lead to great benefits in the steps that follow. Ideally, the food samples are comminuted in the frozen state to improve the quality and ease of homogenization, and to decrease pesticide losses.(56) Certain volatile (e.g. dichlorvos) and unstable pesticides (e.g. dithiocarbamates) are completely or partially lost during homogenization at room temperature.(57) The addition of dry ice is a common
approach to maintain cold temperatures and it also acts to introduce a dispersant which improves the homogenization process.\(^{52}\) Other options are to perform the homogenization in a cold environment or to precool the mixing surfaces and work quickly. Otherwise, a special cryogenic mill may be used, but these devices are generally more applicable to small sample sizes.\(^{58}\) The quality of the chopper and the use of an appropriate sample size in relation to the capacity of the chopper volume are also important factors in achieving the most homogeneous samples.\(^{59}\) Even if all precautions are taken, certain matrix types and pesticides of interest may give more variable results than others. For example, Hemingway et al. found that cypermethrin homogenized in cabbage gave more reproducible results than in apple.\(^{60}\)

### 2.2 Extraction

The extraction procedure begins the process to separate the analytes from the matrix and present the material in a form that can be more easily analyzed. Extraction strategies in multiclass, multiresidue analysis may be designed to (1) employ exhaustive extraction steps to achieve the desired wide range of analytes and rely on more postextraction cleanup steps to improve selectivity or (2) divide the analytes into different classes and utilize several selective extractions to cover the overall polarity range. Most laboratories opt for the former means to reduce effort in extraction, often at the expense of more effort in cleanup prior to analysis. However, cleanup steps can often achieve a higher degree of selectivity than most extraction steps because extraction frequently requires stronger measures to overcome analyte–matrix interactions and to reach small pores in the matrix. This reduces the degree of analyte/matrix selectivity that can be achieved in the extraction procedure.

The choice of solvent generally determines the selectivity of the extraction. With the introduction of instrumental techniques that control pressure and/or temperature of the solvent during extraction, a new way of extraction is emerging. The overall approach may be termed PFE, which consists of SFE,\(^{61–64}\) microwave-assisted extraction (MAE),\(^{65–67}\) and pressurized liquid extraction (PLE),\(^{68–70}\) which is also referred by names such as accelerated solvent extraction (ASE),\(^{71–74}\) pressurized solvent extraction (PSE), and enhanced solvent extraction (ESE). Of course, the extraction concept is the same independent of these approaches, but the use of these techniques to affect the dielectric constant, viscosity, and other properties of solvents can provide benefits in achieving the desired analyte solubilities, extraction kinetics, solvent-to-sample ratios, and a higher degree of selectivity. These techniques can also be useful to obtain more stringent conditions to help overcome matrix–analyte interactions.

Traditionally, liquid solvents at room temperature and pressure are used in the extraction of pesticide residues in solid samples. Table 7 provides some of the properties of typical solvents that are commonly used in the analytical laboratory for pesticide analysis. The important properties of the solvents in analytical applications include polarity (as estimated by the dielectric constant, \(\varepsilon\)), boiling point, density, miscibility with other solvents, viscosity, safety, and cost. The combination of these solvents at room temperature and pressure can provide a reasonable degree of control in the desired properties, but this ability is small when compared with the possibilities of adding the dimensions of pressure and temperature to the equation for the same solvents.

Pressure and temperature control also permits the inclusion of unconventional solvents, such as carbon dioxide and other substances which are gases at room temperature and pressure. A pressurized fluid that becomes a gas after extraction saves the trouble of performing time-consuming and wasteful solvent evaporation steps prior to analysis. Many instrumental techniques reduce labor and variability through automation. Furthermore, sample size reduction and a higher degree of selectivity in the extraction can reduce or eliminate the cleanup steps.

of the extract. The use of less solvent per fixed sample size by controlling pressure, temperature, and/or addition of gaseous co-solvents can also ease post extraction procedures (e.g. solvent evaporation and water removal in GC applications).

Despite the advantages of SFE, PLE, and MAE in some respects, traditional liquid-based methods at room temperature and pressure have advantages of their own. Traditional extraction methods are easy and do not require the added expense of purchasing and maintaining instrumentation. Fewer parameters to control and known expectations based on accumulated knowledge makes traditional method development less complicated. Liquids often serve as a good medium to homogenize samples and often limit analyte degradation and volatilization. In aqueous systems, the use of salts, acids, and bases often has a strong effect in extraction and partitioning. Unfortunately, the inherently wide polarity range of analytes in multiclass, MRMs handicaps their own. Traditional extraction methods are easy and do not require the added expense of purchasing and maintaining instrumentation. Fewer parameters to control and known expectations based on accumulated knowledge makes traditional method development less complicated. Liquids often serve as a good medium to homogenize samples and often limit analyte degradation and volatilization.

Prior to the 1990s, water samples were more frequently extracted with liquid–liquid extraction (LLE) using an immiscible solvent, such as dichloromethane, but SPE has become the prevalent approach for water now. However, LLE can be adapted to use smaller volumes of organic solvents and increase convenience. The most common solvents used for extraction in multiclass, multi-residue analysis are acetone, acetonitrile, ethyl acetate, and methanol. For high-moisture samples, the water in the sample incorporates with miscible extraction solvents and helps to improve recoveries of many pesticides. In the case of ethyl acetate (or dichloromethane and hexane), wet samples are frequently mixed with a drying agent, such as sodium sulfate, to remove water. In SFE, a similar procedure using diatomaceous earth or salt desiccants for wet samples is followed to prevent adverse effects of water freezing-out the water (supercritical CO₂ is only slightly miscible with water).

Water is considered the first choice as the extraction solvent for safety, cost, and environmental reasons, but water is not very useful by itself in typical multiclass, multi-residue applications. The less polar analytes are not extracted well with water, even at relatively high temperatures, but a host of problematic water-soluble matrix components often make cleanup more difficult. Concentration steps are usually needed prior to analysis, and evaporation of water is very slow and relatively volatile pesticides are lost at conditions needed to evaporate water, even during lyophilization. Also, many pesticides degrade more rapidly in water than in other solvents, and several other pesticides will either precipitate or otherwise interact with the glassware rather than remain in the water. It is possible to decrease the polarity of water by increasing the temperature and pressure, but then degradation is increased and polarity advantages of water are lost.

In extracts that contain water, however, the water should be concentrated or removed before analysis using conventional GC techniques (water is often not a problem in LC methods). Water can be separated from the mixture by exposing the solution to a drying agent, addition of salt, freezing-out the water phase, and/or liquid–liquid partitioning with water-immiscible solvent(s). The organic phase is then usually concentrated by evaporation, which is why low-boiling solvents are desired to reduce the time of the extract concentration step. SPE is also utilized to separate the solutes from an aqueous solution. An advantage of SPE is that it concentrates the analytes as they partition out of the aqueous solution onto the solid sorbent. Thus, the concentration step after SPE is shortened or eliminated. Some polar analytes may break through SPE sorbents if the use of excessive aqueous volumes is attempted, but the problematic pesticides tend to be the same ones that only partially partition into the organic phase in LLE.

The use of ethyl acetate as the extraction solvent avoids the water removal and partitioning steps, but ethyl acetate tends to be a less selective (or more exhaustive) extraction solvent than solvents that are completely miscible with water. Thus, ethyl acetate methods commonly require a solvent-intensive GPC step to remove co-extractives, even in the case of nonfatty matrices. Less cleanup is usually needed for methods that use acetone and acetonitrile. Acetonitrile is particularly useful in the case of fatty foods because fats have a lower solubility in acetonitrile than several other solvents.

2.2.1 Solid-phase Microextraction

A novel approach using sorbents in relatively selective extractions is solid-phase microextraction (SPME). Figure 5 shows a drawing of an SPME fiber. The key advantage of SPME is the simplicity of operation; all that is required is sequentially to place a fiber into a liquid or gaseous sample and then into a chromatographic injector. SPME works by coating a small fiber with a liquid polymer or solid phase and exposing this coated fiber to the sample. The analytes (and other chemicals)
fiber partitioning and lead to inaccurate quantitation, results empirically as in other approaches with the use of known, but it is easier and more common to quantify analytes quickly partition into the sorbent, or longer times (e.g., 1 h) may be needed in an attempt to decrease the LOD and increase the range of analytes. Quantitation can be performed from fundamental thermodynamic equations if all parameters are known and the system is at equilibrium. This is also true if the kinetics of the system are well known, but it is easier and more common to quantify results empirically as in other approaches with the use of calibration standards. Matrix components can greatly affect partitioning and lead to inaccurate quantitation, but the method of standard additions or use of standards in matrix may help overcome this problem.

In multiclass, multiresidue applications, SPME can be too selective and not possess a sufficiently wide polarity range to extract the targeted analytes. At the same time, SPME may not be selective enough because it may extract too many matrix interferences. At this time, automated SPME systems and a few different fiber coatings that cover different ranges in polarity are commercially available. SPME can be very useful in applications of relatively clean air and water matrices for a reasonable number of pesticides, but direct extraction of complex samples is often problematic with SPME. To reduce problems of nonvolatile matrix components in liquid samples, the fiber may be placed in the headspace of the liquid. The amount of pesticide analyte extracted will not be altered, but it may take an exceedingly long time for the equilibration process between the liquid, headspace, and fiber coating phases. Overly small sample volumes can also be a disadvantage in SPME, and consequently the LOD may also be too high in SPME for some applications. In the future, the use of a coated capillary, as in a GC column, rather than a coated rod as in SPME, will permit larger volumes and shorter analysis times by being able to flow the sample through the capillary.

Owing the frequently less than 100% partitioning of analytes into the fiber, the recovery concept of extraction is not necessarily an appropriate indicator in SPME. However, recovery has traditionally been an indicator of accuracy in a method. Therefore, SPME may only be used in limited quantitative applications for pesticide residues, but it may become a prominent screening approach owing to its ease of use and potentially fast operation. SPME can also be very useful in determining properties of pesticides such as Henry’s law constants and in process monitoring systems.

2.2.2 Extraction of Gaseous Samples

Analytes are extracted from gases by precipitation under cold conditions (e.g., cryofocusing), adsorbed by a solid (e.g., SPE), or absorbed into a liquid (e.g., bubbling into a liquid). SPME (a liquid absorption or solid adsorption approach, depending on the fiber coating) can be useful in the extraction of small volumes of gases or in air screening applications, but traditional air sampling approaches remain prevalent in environmental air studies. The use of polyurethane foam (PUF) for large-volume air sampling is an effective approach for a variety of airborne pesticides. Other common solid-phase adsorbents include Tenax®, carbon, silica-based sorbents, and polymers. The combination of low temperature with adsorption or absorption extraction methods can be used to increase extraction efficiencies.

2.3 Cleanup

The separation of analytes from undesirable matrix components, or “cleanup” of sample extracts, can be accomplished through liquid–liquid partitioning, liquid–solid partitioning, size-exclusion chromatography (SEC) or GPC, dialysis, distillation, centrifugation, filtration, precipitation, immunoaffinity, or other techniques that take
advantage of differences in the physicochemical properties of the analytes and the interferents. Owing to the way in which analysts choose to compartmentalize the overall multiresidue, multiclass strategy, different laboratories that use the same extraction methods may diverge during cleanup for different pesticide groups.

2.3.1 Liquid–Liquid Partitioning

Liquid–liquid partitioning has been an effective cleanup technique for over a century, and is still commonly used today. However, its disadvantages include the typical use of large volumes of potentially hazardous solvents, the necessity for concentration steps afterwards, the generation of hazardous waste, labor-intensive and/or time-consuming procedures, potential occurrence of emulsions, the need for a laboratory hood and storage space, added external source of potential sample contamination, and the dishwashing requirements of the many pieces of glassware. The traditional wet chemistry methods are slowly being replaced by newer methods that are more easily automated, take less labor, space, and time, and use less solvent and glassware. Despite the encroachment of newer cleanup approaches, however, liquid–liquid partitioning will remain a viable approach.

Dichloromethane and ethyl acetate are particularly useful solvents for the cleanup of acid–base pesticides in aqueous extracts. Changing the pH of the aqueous phase can help either to separate ionic pesticides from neutral compounds or to separate neutral pesticides from ionic compounds. The use of chlorinated solvents, such as dichloromethane, has become a concern among many laboratories for waste disposal and safety reasons, but its immiscibility with water, ease of evaporation, solubilizing power, and greater density than water (hence it settles as the lower phase in a separating funnel) make dichloromethane a difficult solvent to disperse.

Liquid–liquid partitioning can help remove fats from water and/or acetonitrile solutions with hexane or immiscible ethers. One of the drawbacks for removing lipids with liquid–liquid partitioning approaches in multiclass, MRMs, however, is that lipophilic pesticides also tend to partition into the same phase as the lipids. A partitioning factor, or $P$ value, can be used to correct for the known percentages of affected pesticides that partition with the fats under predetermined conditions. However, this can lead to higher detection limits (owing to the analyte losses) and greater margins of error. Also, methods should achieve pesticide recoveries $>70\%$ to meet most QA criteria.

2.3.2 Gel Permeation Chromatography

The development of GPC, also known as SEC, in the 1970s caused the use of liquid–liquid and liquid–solid partitioning to diminish. GPC achieves fewer losses of pesticides when separating fats and other large molecules by taking advantage of the molecular size differences of the larger chemicals from the smaller pesticides. Because many pesticides tend to have relatively similar molecular sizes, they can generally be collected in a single fraction. Another advantage is that the GPC column can be re-used many times and is easily automated, unlike typical uses of adsorbent columns. Unfortunately, many matrix co-extracts of similar molecular size as the pesticides are not separated in GPC, and other cleanup techniques may still be required afterwards. Practical disadvantages of GPC include the very large volumes of potentially hazardous solvents involved, the generation of waste, the need for post-GPC concentration steps, and the costs associated with purchase and maintenance of instrumentation and columns. In recent years, new gel materials, more benign solvent combinations, and miniaturized columns have improved practical aspects of GPC, and it remains the most common means to remove high- and very low-molecular-weight components from food and environmental samples.

2.3.3 Distillation

Another way to remove fats and other relatively non-volatile materials is sweep codistillation (SCD). Essentially, SCD can be likened to preparative-scale GC in which the relatively volatile pesticides are separated from nonvolatile components. Nitrogen gas is generally the mobile phase and silanized glass beads or other materials may be used as the stationary phase. SCD was commercially developed in the 1960s, but owing to variability of results with the approach, few scientists continued to use the technique.

More advanced instruments were developed in the 1980s which regenerated interest in the approach. Thermally labile pesticides may be lost at the temperatures involved ($\sim 250^\circ \text{C}$) and separate cleanup may still be required in some applications. In the analysis of OCs in fatty matrices, SCD has been shown to provide equally valid results as GPC and Florisil adsorption. However, with the use of current commercial instrumentation, SCD gave a 10-fold higher sample throughput and 40-fold lower solvent consumption than the other two approaches.

2.3.4 Solid-phase Extraction

The most common and diverse approach to cleanup (and extraction of water samples) in pesticide residue analysis is SPE. For several decades, liquid–solid partitioning has been an option for analytical chemists to separate components from a solution, but prior to the introduction of commercial SPE cartridges in the 1970s, liquid–solid
partitioning was performed using columns prepared by the analyst in the laboratory. The choice of sorbents for cleanup at that time were essentially limited to normal-phase applications with alumina, Florisil, silica, and charcoal. The poor reproducibility of the sorbents from batch to batch, their need for activation/deactivation, and the manual column preparation procedures involved led to variable results.

The advent and growth of HPLC in the late 1960s and 1970s led to more choices and better reproducibility of stationary phases. Reversed-phase applications with C₈ and C₁₈ stationary phases and the commercial introduction of premade disposable cartridges initially made SPE a useful technique for the extraction and cleanup of aqueous samples and extracts. Over the last 20 years, improvements and diversifications in SPE formats, sorbent types, and apparatus have made SPE a widely used approach for a variety of applications, including multiclass, multiresidue analysis of pesticides.

SPE cartridges or disks can be likened to very low-resolution HPLC columns in that similar stationary and mobile phases are used. However, HPLC is not always helpful in determining conditions for SPE, and vice versa. Typical particle sizes in SPE are 40 µm, and the plastic cartridges are generally packed with 0.1–1 g of sorbent in wide tubes, whereas higher density packing of 5-µm stationary phase particles in narrower columns is currently prevalent in HPLC. Larger LC columns and typical injection volumes > 1 mL can be very useful for the cleanup of extracts in semipreparative LC. With automated systems, SPE can be likened to semipreparative LC because the procedures and materials can be similar. The greater separation power of semipreparative LC, however, provides higher potential for better selectivity by collecting heart-cut fractions for later analysis or direct analysis in coupled analytical systems.

The choice of reversed-phase, normal-phase, and ion-exchange media in SPE is very diverse, and Table 8 lists some of the more popular SPE applications for cleanup of multiple pesticides. The modes of operation involve all options of either retaining, or not retaining, the analytes and/or matrix interferences through the selection of appropriate sorbents and solvents. SPE formats can be cartridges or membrane extraction disks of various sizes designed for single- or bi-directional flow. Recently, SPE has even been commercialized in disposable pipet tips for convenient miniaturized applications.

The introduction of GCB and polymer-based sorbents, such as DVB, has led to modifications of some multiclass, MRMs for pesticides in water, soils, and foods. Carbon has been known as an excellent liquid–solid partitioning sorbent for many years, but carbon was notorious among chemists owing to the great number of charcoal types, sources, and irreproducibility. The advantages of certain polymer-based sorbents in reversed-phase applications over silica-based sorbents include higher possible flow rates, wider pesticide polarity range, wider pH range, and allowance of the cartridge to go dry without losses. This is useful in applications, because water can be removed from the extract by drying the cartridge with flowing gas prior to elution of the analytes with the chosen solvent(s).

The choice of sorbent–solvent combination in SPE for cleanup of extracts is much like choosing the extraction solvent for certain pesticide(s) in a particular matrix. A great deal of experience with SPE and knowledge about the chromatographic behavior of the analytes and matrix co-extractives can save much effort in method development using SPE. However, trial and error is the more common approach to method development using SPE because unpredictable results and/or subtle differences may occur between different stationary–mobile phase combinations. Also, in multiclass, multiresidue applications, the need to maintain a wide polarity range of analytes does not allow the analyst to achieve the best degree of selectivity for the analyte as is possible in SPE (unless the analyst chooses to divide the extract into a series of separate cleanup procedures).

This polarity range dilemma can lead to unconventional SPE methods. For example, the use of a carbon or alumina (traditionally normal-phase sorbents) with acetonitrile (a solvent more common in the reversed-phase format) may separate interferences from analytes reasonably well in multiclass, multiresidue applications. Also, stationary phases used in ion-exchange approaches, which have the strongest interactions in water, are used with nonaqueous mobile phases in multiclass, multiresidue procedures. The use of liquid–solid partitioning with charcoal, silica, Florisil and/or alumina is also possible to aid in the removal of lipids, but semipolar pesticides require large elution volumes and many relatively polar pesticides are completely retained by these adsorbing phases. The elution volumes and recoveries of different pesticides

from different columns and mobile phases are outlined in PAM 1. The recoveries of a large number of pesticides using the “Luke” and other methods tested by the FDA are also listed in PAM 1.

2.3.5 Automation

Off-line SPE approaches are generally conducted manually in batches of 8–12 using SPE vacuum manifolds. Laboratories that conduct routine analysis have begun to use automated approaches in general, and SPE is no exception. A major advantage of SPE is that it can be automated and conveniently combined with extraction and/or analysis in a single instrumental arrangement. The use of on-line, or coupled, LC approaches (including SPE) permits automation of analyses to reduce labor and typically increase sample throughput.

In SFE, it is common to collect and concentrate the extracts on a solid-phase trap, and a higher degree of selectivity can be achieved by using a sorbent used in SPE applications, such as C18, as the trapping material in SFE rather than an inert surface or solvent. In pesticide and other analytical applications of SFE, it is often preferable to use an SPE sorbent to attain higher trapping efficiencies, lower solvent consumption, and greater selectivity. By eluting the analytes with a certain volume of appropriate solvent(s), a simple and convenient SFE/SPE procedure can be conducted. PLE instruments also may permit the automatic combination of extraction and cleanup. GPC has also been combined with SPE, but automation and coupling of liquid–liquid partitioning methods are uncommon.

The approach to coupling techniques may be taken a step further by linking the SPE step with an analytical instrument. The introduction of the extract into a GC or HPLC instrument immediately after SPE is possible, but a small concentration step is more commonly performed in the attempt to lower the LOD. Direct coupling of GPC to the analytical instrument is very rare in pesticide residue studies because large solvent volumes must usually be evaporated after GPC, and in the case of reversed-phase HPLC the types of solvents used are not typically amenable.

2.3.6 Matrix Solid-phase Dispersion

Another way to combine SPE with the extraction process is to utilize matrix solid-phase dispersion (MSPD). In MSPD, the sample is mixed with a solid-phase material which separates matrix interferents from the pesticide analytes during extraction. Thus, cleanup is performed at the same time as the extraction.

A form of MSPD is nearly always conducted in SFE and PLE to disperse the sample, absorb water, and/or retain unwanted matrix components. A relatively inert sorbent, such as diatomaceous earth, is used for sample dispersion and water absorption, but Florisil, alumina, silica, or other sorbents may be used to retain matrix components. Conversely, the choice of sorbent–solvent combination and extraction conditions may be designed to retain the analytes and remove the interferents. This technique, dubbed inverse extraction, is followed with a second set of extraction conditions to extract the analytes after the interferents have been removed.

MSPD has been evaluated in pesticide applications, but drawbacks include the small sample size involved (~0.5 g) and the high cost of sorbents, especially if the sample size is increased. MSPD in multiclass, multiresidue analysis of pesticides at most uses a 4 : 1 sample-to-sorbent ratio. The sorbents are generally the most expensive material cost in multiclass, multiresidue approaches that involve SPE.

3 ANALYTICAL SEPARATIONS AND DETECTION

Any approach applicable to the analysis of organic molecules (and a few inorganics) may be useful in the analysis of pesticides, but MRMs (and even single analyte methods) nearly always require an analytical separation prior to the detection of the different analytes. Certain screening techniques may not involve a separation step, but positive findings would then usually require a determinative method to quantify and identify the pesticide(s). Techniques that involve optical spectroscopy or electrochemistry may provide a degree of selectivity, but such detection methods are rarely used in residue methods except as detection after chromatographic separations.

At this time, nearly all analytical methods utilize GC or HPLC as the separation step, but other column chromatographic techniques and CE are also reasonable options for conducting separations. Planar or thin-layer chromatography (TLC) may be acceptable in some applications, but currently TLC is typically used as an analytical approach only when the analyst places a higher priority on sample throughput than on achieving the type of higher quality results possible with more modern methods. However, TLC can be very useful in screening applications owing to its potential for high sample throughput and ability to provide better separation than several other screening approaches. Fast GC or flash GC, in which the GC conditions are optimized for speed, is another chromatographic option but the this type of approach has not been utilized in routine applications.

The development of supercritical fluid chromatography (SFC) and experimentation with mobile phases consisting of dense gases, supercritical fluids, and/or
liquids at high temperatures and pressure has led some analytical chemists to think in terms of “unified chromatography”.\(^{(114)}\) Fundamentally, there are no stationary phase boundaries between GC, HPLC, and SFC, and the mobile phases are actually a continuum of fluids. Just as pressure and temperature control have added new dimensions in extraction processes, the control of pressure and temperature in chromatography coupled with the diversity of mobile and stationary phase options may lead to extraordinary possibilities in separations. For example, SFC has been demonstrated to separate an exceptionally wide polarity range of pesticides using a single set of conditions.\(^{(115)}\) Pesticides that are currently analyzed by either GC or HPLC may be determined with a single unified chromatographic system. At this time, the lack of rugged injection and sensitive analyte detection processes has been the limiting factor in pesticide residue applications in this type of approach.

For detection, MS is rapidly becoming the method of choice for multiclass, multiresidue analysis owing to its many advantages, recent improvements in technology, and availability of cost-effective commercial instrumentation. Detection systems in general are continually being improved and, in combination with the improvements in chromatographic instruments and techniques, exceptionally low LODs are possible for pesticide residues.

### 3.1 Gas Chromatography

GC, also sometimes referred to as gas–liquid chromatography (GLC), is the most common method for the analytical separation of pesticides in multiclass, MRMs. The possible number of theoretical plates in separations and the variety and capabilities of the detectors that can be coupled to GC usually make it the first choice for analysis. Some laboratories decide to limit the types of analyses conducted by using GC for nearly all analyses. For example, certain pesticides may be included in a multiresidue GC method despite the fact that HPLC may provide better results, such as in the case of thiabendazole.\(^{(9)}\)

#### 3.1.1 Derivatization

The analysis of thermally labile pesticides is not possible using GC methods unless the analytes are converted into a more volatile and stable form. Analysis of the analyte in its natural state is the preferred approach in any method, and derivatization leads to extra procedural steps and other potential complicating factors. However, until recent advances in LC/MS, chemical derivatization for GC analysis was essentially the only option in the case of thermally labile pesticides that did not give high absorbance or fluorescence signals. At this time LC/MS continues to become more sensitive, more rugged, and less expensive, but chemical derivatization remains a common approach for targeted thermally labile pesticides using GC analysis.

If derivatization is performed in multiresidue, multiclass strategies, a portion of the original extract is usually separated from the fraction that will be used in the analysis of the larger number of pesticides. The extracts may need separate cleanup steps, but it is sometimes possible to recombine the different extract fractions for analysis with the same GC method.\(^{(116)}\) Common derivatization procedures for GC methods involve the alkylation of acids which may also serve to add functional groups that achieve highly sensitive detection with the chosen detector. Other examples include the use of pentafluorobenzyl bromide to link with carbendazim (degradation product of benomyl and thiophanate-methyl)\(^{(117)}\) among other single-class pesticide analysis schemes.\(^{(118,119)}\)

One problem with derivatization is the possible lack of selectivity in the reaction which can make a host of other derivatized compounds. In single analyte methods, this is not usually a problem, but in multiresidue separations, the other derivatized compounds are more likely to interfere with detection of other analytes. Highly resolved separations and/or universally selective detection methods, such as MS or AED, may overcome this problem, but it is more common to follow single-analyte methods when performing derivatization.

#### 3.1.2 Gas Chromatography Separations

The selection of GC conditions for the analysis of pesticides mostly depends on the targeted pesticides and chosen detector(s). A variety of sources are available for relative retention indices of pesticides on different stationary phases and conditions.\(^{(1,127,120)}\) The choice of the column may not make a significant difference in the final quantitation of most pesticides,\(^{(9)}\) but relatively polar pesticides often give better peak shapes using relatively polar stationary phases, whereas nonpolar pesticides can give good peak shapes in a variety of columns. The most common GC stationary phases in pesticide analysis consist of dimethylpolysiloxane or methylpolysiloxane with 5–50% phenyl, cyanopropyl, or cyanopropylphenyl. The use of packed GC columns has virtually been universally replaced with the use of capillary columns, which may be narrow-bore (0.25 mm i.d.), wide-bore (0.32 mm i.d.) or mega-bore (0.53 mm), or of other sizes depending on the application. Capillary columns narrower than 0.25 mm i.d. are rarely used in food or environmental multiresidue applications, and guard columns (also known as retention gaps) are often useful in the analysis of complex extracts.

Injection of 1–3 µL of extracts is typical using split/splitless techniques, but on-column injection has
advantages for some pesticides. Larger injection volumes (0.01 – 1 mL) are now possible with some current GC injection devices, but large-volume and/or on-column/cold injection methods in GC typically require more column maintenance than split/splitless volume techniques. Recent advances in GC instruments in addition to large-volume injection consist of exceptionally fast separations, improved columns, electronic pressure control, retention time locking, and other capabilities. These topics are discussed in section 55 of this Encyclopedia.

3.1.3 Matrix Enhancement Effect

An important issue in the multiresidue analysis of pesticide residues in GC, particularly for polar OPs, is the “matrix enhancement effect”. This effect occurs owing to polar functional groups on the pesticide analytes interacting with silanol, metal ions, and other active sites in the surfaces of GC systems (mainly from glass in the injection liner). In the presence of matrix co-extractives which tend to fill the active sites, the matrix enhancement effect results in an increased analyte injection efficiency (and consequently a higher signal) for certain pesticides in the presence of matrix than in solvent solutions which contain no matrix. Thus, if pesticide solutions only in solvent are used for calibration standards, the recoveries of matrix spikes and concentrations of the affected pesticides in sample extracts are systematically overestimated. For low-level spikes of affected pesticides, it is not unusual to observe enhancements of >150%. Table 9 provides results that show which pesticides are (and are not) affected by the matrix enhancement effect. These results are averaged from a number of food analyses over the course of time using different GC detectors as part of the Swedish MRM. Owing to the nature of multiclass, multiresidue analysis, it is difficult to completely overcome this effect for polar OPs. The use of deuterated internal standards, on-column or high-flow injection, coating the injection liners with column phase, or method of standard additions can overcome or compensate for the matrix enhancement effect, but the most practical and common way to avoid the problem is to use calibration standards in blank matrix extracts. Blank extracts are usually obtained from real samples in the monitoring program that have been shown to be free of residues, but blank field samples, which are often included in some studies anyway, may also be used as material for matrix-matched calibration standards.

3.1.4 Selective Detectors

For detection, the flame ionization detector (FID) and photoionization detector (PID) are rarely used in pesticide residue applications, in part, owing to the lack of selectivity, but the use of traditional selective detectors is a very common approach to multiresidue analysis of pesticides. The use of a halogen-selective detector [ECD, electrolytic conductivity detector (ELCD), or halogen-specific detector (XSD)] in conjunction with a phosphorus- [flame photometric detector (FPD), pulsed flame photometric detector (PFPD), NPD], sulfur- [FPD, PFPD, sulfur chemiluminescence detector], and/or nitrogen-selective detector (NPD, PFPD) is a common approach to cover a wide range of pesticides and to reduce sample cleanup. The AED is another element-selective detector, but it is useful for a number of elements simultaneously. The PFPD is also useful for the selective detection of 28 elements (up to two simultaneously), and can provide lower LODs at a lower cost than an AED.

Some multiclass, multiresidue schemes use up to five detectors in separate GC analyses which are selective for halogens, nitrogen, phosphorus, sulfur, and other elements, plus MS for confirmation. Thus, each sample extract requires five GC injections, plus HPLC methods, to analyze and identify the wide range of pesticides targeted for analysis. Some analysts choose to split the flow of a GC separation to two detectors which minimizes the number of injections, but this approach also reduces the amount of analyte that reaches the detector and complicates separations by using the same column for all analytes.

3.1.5 Gas Chromatography/Mass Spectrometry

The most widely regarded approach to accomplish the analysis of as many pesticides as possible in as few steps as possible is to use MS detection. MS is considered a universally selective detection method because it detects all compounds independent of elemental composition and further separates the signal into mass spectral scans to provide a high degree of selectivity. Unlike gas chromatography/atomic emission detection (GC/AED), gas chromatography/mass spectrometry (GC/MS) may provide acceptable confirmation of the identity of analytes without the need for further information. This reduces the need to reanalyze a sample into a separate GC system for pesticide confirmation. Through the use of selected ion monitoring (SIM), efficient ion-trap or quadrupole devices, and/or tandem mass spectrometry (MS/MS), modern GC/MS instruments provide LODs similar to or lower than those with selective detectors, depending on the analytes, methods, and detectors.

MS detection does not necessarily require as highly resolved GC separations as in the case of selective detectors because the likelihood of an overlapping mass spectral peak among pesticides with the same retention time is less than the likelihood of an overlapping peak from

the same element. Unfortunately, this advantage cannot always be optimized because in SIM and current gas chromatography/tandem mass spectrometry (GC/MS/MS) methods, the ability to detect two analytes at once increases the LOD of each analyte. Overlapping full-scan mass spectra can also pose problems with confirmation, so baseline resolution of as many pesticides as possible is still desirable. Low-bleed capillary columns are typically used in GC/MS systems to reduce background noise, but until recently, only nonpolar phases had low-bleed properties. The commercial introduction of relatively polar low-bleed phases has improved the capability to achieve good separations and peak shapes for the relatively polar pesticides at the same conditions for nonpolar pesticides.

Another reason that it is difficult in practice to achieve the lowest LOD possible for more than about 100 pesticides in a single injection by MS and MS/MS is that some pesticides provide lower LODs when using positive ion chemical ionization (PCI) while others are better detected in electron impact ionization (EI) or negative ion chemical ionization (NIC) modes. It is not uncommon for analysts to use a series of injections in GC/MS to best cover the large number of pesticides possible with the approach. Sequential EI and PCI modes used in the same run is possible with some instruments, but this approach is seldom used.

The precision of GC/MS for analysis of pesticide residues generally varies from 5 to 20% RSD, which is similar to that in approaches using other GC detectors. Quantitation with modern GC/MS instruments suitably meet the needs of most quantitative applications. However, some chemists have decided to use MS only for applications involving the determination of unknowns, confirmation of pesticide identities, and/or rapid screening.

3.1.6 Pesticide Identification

Confirmation criteria in pesticide residue analysis are a subject of debate, depending on the application, but it is generally recognized that human judgment is required in the final decision. Criteria to consider in MS include: (1) proper GC retention time; (2) three ions of correct mass/charge (m/z) ratios; (3) adequate signal-to-noise ratios; and (4) absence of similar signal in blank samples (to indicate no contamination or carryover). The definitions of “proper” “correct” and “adequate” are based on the need and importance of the result. In any case, some pesticides do not provide three ions in their spectra, or the ion ratios for some spectra may be more variable than deemed acceptable if strict definitions are used. Other factors are sometimes taken into account, such as chromatographic peak shape, sample history, and/or analyst experience. In these difficult cases, information from other analyses, perhaps using other ionization modes in MS or even infrared spectroscopy, are sometimes performed to gather more evidence. The combination of an element-selective detector and MS can provide excellent information for determining the presence of an analyte, or just as important, eliminating the chance that a pesticide is present. The added selectivity gained in the use of multiple mass spectrometry (MSn) can also weigh heavily in confirmation of pesticide identity despite the possible lack of three ions of defined ratios. Some older methods of confirmation, such as the use of two different stationary phases in GC, are no longer acceptable in many cases, especially if the results will be used for regulatory purposes.

3.1.7 Direct Sample Introduction

Conventional wisdom maintains that elimination of cleanup steps in an analysis reduces the quantitative capabilities and/or ruggedness of the analysis. The effects of matrix and/or lack of ruggedness are often the biggest limitation of using the modern sensitive and selective detectors in GC analysis of complex extracts. The detectors may be capable of discriminating low-level analytes from potentially high-background interferences, but the GC injector can become contaminated with nonvolatile components after only a few injections unless cleanup is performed. A recent advance, direct sample introduction or “dirty sample” injection (DSI), has addressed these factors.

DSI improves the ruggedness of the approach because nonvolatile components that can contaminate GC columns and MS sources remain in the disposable sample vials used for injection. Figure 6 shows a drawing of a DSI device inside a GC injection port. In DSI, samples are extracted by the means available, and up to 30 µL of the liquid extracts are placed in a disposable vial. Essentially, DSI operates by thermal desorption of sample extracts from the vial placed in the injection port into the GC column. This is not unlike SPME, which also does not contaminate the GC system (because nonvolatile components remain in the fiber coating during injection), but extraction methods in DSI can provide a wider analyte polarity range than SPME. This is because DSI operates solely on analyte volatility whereas SPME depends on partitioning ratios into the fiber coating. Furthermore, the expensive, reusable SPME fiber remains contaminated with nonvolatile materials after injection whereas the inexpensive microvial in DSI is disposable.

The DSI approach for complex extracts requires the use of selective detection to discriminate the pesticide analytes from the other semivolatile matrix components in the extract, but the use of selective detectors, such as PFPD, and also MS and MSn, can meet this challenge. The quantitative aspects of DSI

MULTICLASS, MULITRESIDUE ANALYSIS OF PESTICIDES, STRATEGIES FOR

23
with GC/MS/MS has been demonstrated for 23 diverse pesticides in fruits and vegetables.\(^{138}\) Recoveries were near 100% (ca. 10% RSD) with the approach, and the LODs were \(<1\text{ ng g}^{-1}\) for the pesticides.

### 3.2 High-performance Liquid Chromatography

The common need to achieve separation of so many analytes in multiclass, multiresidue applications tends to preclude HPLC as the primary means of analytical separations. However, HPLC is often an integral part of an overall analytical scheme in which the approach is used for the analysis of single classes of pesticides not amenable to GC.\(^{1,27,53}\) Typically, reversed-phase high-performance liquid chromatography (RPHPLC) is employed for the thermally labile, semipolar and polar pesticides. Normal-phase HPLC is capable of separating nonpolar and semipolar pesticides,\(^{139}\) but these types of pesticides are not typically thermally labile and the GC methods often give better separations and lower detection limits. Some laboratories may choose to derivatize thermally labile pesticides for an overall method relying on GC analysis,\(^{140}\) but it is generally preferable to detect the analytes as they occur in the sample. Thus, HPLC is a common alternative to GC derivatization methods.

Liška and Slobodník reviewed and compared the use of GC and LC methods for the analysis of polar pesticides in water.\(^{141}\)

HPLC is a more rugged approach than GC owing to the continual rinsing of the system with liquid and simple means of liquid sample introduction. HPLC permits the injection of larger sample volumes (typically 25–250 \(\mu\)L) than GC (typically 1–3 \(\mu\)L), which also helps to improve the sensitivity of HPLC methods. Despite this aspect, LODs in GC methods with selective detectors may be lower than those in HPLC methods (depending on the analysis), despite the much larger HPLC injection volume. A disadvantage of HPLC is the potentially large amount of mobile phase solvent needed and waste generated. However, solvent recycling, newer and smaller packing phases, narrower columns, and slower flow rates are reducing this potential drawback. The articles on HPLC (section 59 of this Encyclopedia) should be consulted for a discussion of these and other aspects of HPLC.

#### 3.2.1 Detectors

HPLC detectors are not as varied as GC detectors. Common HPLC detectors used in pesticides residue analysis include ultraviolet/visible (UV/VIS), fluorescence, and MS detectors, whereas electrochemical detectors are less commonly used. Currently, single-wavelength UV/VIS absorbance is a common approach to detection in HPLC, but this approach is well noted for its general lack of selectivity, especially at low wavelengths, and inability to detect analytes that do not contain chromophores. The diode-array detector (DAD), also called photodiode array (PDA), provides a higher degree of selectivity, but it is also limited to the detection of analytes with chromophores and is usually associated with higher LODs than single-wavelength detectors. Fluorescence is a much more selective and sensitive option for HPLC detection, but few pesticides fluoresce strongly enough to warrant a separate method for their detection, especially in multiclass, MRMs.\(^{109}\) A beneficial feature of spectrophotometry and spectrofluorimetry, however, is their nondestructive nature, which enables them to be combined in series with themselves\(^{142}\) and/or other detection methods (such as MS) to increase the overall selectivity.

#### 3.2.2 Post-column Derivatization

Even though certain thermally labile and nonvolatile pesticides may be amenable to separation in HPLC, their detection can be difficult with traditional detectors if they do not provide a sufficient absorbance, fluorescence, or electrochemical signal. Derivatization of the analyte to improve detection (with any detector) is sometimes the only option to meet desired the LOD. If the pesticide
analyte can be derivatized in a rapid reaction, then postcolumn derivatization can be a useful method for detection in HPLC. Chemical derivatization steps during the sample preparation are an option prior to HPLC analysis, and have the added benefit of permitting longer reaction times, but traditionally GC would be used if HPLC postcolumn derivatization is not feasible. Postcolumn derivatization eases the sample preparation process because separate derivatization steps are not needed, and the pesticides have already been separated by the analytical HPLC column. Because relatively few other reactive compounds are likely to be present at the analyte retention times, the selectivity of the overall approach is further increased.

Fluorescence detection is the most common postcolumn derivatization approach owing to the high sensitivity and selectivity of the detector. A common approach in the postcolumn derivatization process is the reaction of o-phthalaldehyde with amines. Heat or ultraviolet (UV) radiation applied to a reaction bed or length of narrow tubing may be used to drive the reaction. Postcolumn derivatization fluorescence detection in HPLC is useful in the analysis of several amine-containing pesticides, such as carbamates, ureas, and certain organophosphates. In particular, postcolumn derivatization fluorescence detection has become the standard approach for the analysis of N-methylcarbamate insecticides.

3.2.3 Liquid Chromatography/Mass Spectrometry

Owing to the rapid pace of major advances in LC/MS, a number of reviews of LC/MS and its use in the analysis of pesticides has been published in recent years. There has been a strong need for a universal and selective detector such as MS in LC (and other) applications since the advent of the technique. In the 1980s, moving belt, particle beam (PB), and thermospray (TSP) interfaces were used with limited success in the analysis of pesticides. With the improvements and commercialization of liquid nebulization interfaces and atmospheric pressure ionization (API) for MS, the need for derivatization of thermally labile pesticides for GC or HPLC detection is expected to wane. Applications of liquid chromatography/particle beam mass spectrometry (LC/PBMS) and liquid chromatography/thermospray mass spectrometry (LC/TSPMS) for pesticides have essentially been replaced with techniques using atmospheric pressure chemical ionization (APCI) and electrospray (ESP) ionization, also known as ionspray (ISP), techniques. Modern LC/MS instruments capable of ESP and APCI modes, and that now fit on a benchtop, provide lower LODs, more facile and rugged operation, and lower costs than ever before. LC/MS instruments are still several times the price of a traditional system, but the identification and universal detection capabilities of MS (or MS^n) make it a powerful analytical tool.

Many of the same general advantages and disadvantages of GC/MS are prevalent in high-performance liquid chromatography/mass spectrometry (HPLC/MS), but a higher degree of complexity and more limitations are associated with HPLC/MS. Most notably, the current main ionization modes in LC/MS (ESP, APCI) can give very different ionization levels and responses for different pesticides. This is further complicated by the choice of positive or negative ionization in each of the two ionization modes which leads to a choice of four possible LC/MS operating conditions (+/- ESP, +/- APCI), none of which can currently be interchanged during the course of a run. This further limits the utility of LC/MS for multiclass, multiresidue pesticide methods in a single run. Furthermore, the use of the soft ESI and APCI ionization techniques and easy formation of analyte–salt adducts mean that separate injections from the quantitation method may still be needed to conduct confirmation through collision-induced dissociation (CID) of the analytes. Also, owing to salt build-up in the interface, high concentrations of nonvolatile salts should not be added to the mobile phase in LC/MS, thereby diminishing the ability to optimize buffers and ion-pairing reagents which are helpful in some pesticide applications. Also, lower flow rates are often used in LC/MS, particularly with ESP unless split flow or other precautions are taken, which often necessitates the use of more precise pumps and smaller columns than in traditional HPLC applications. However, this aspect may in fact be advantageous because narrow columns, smaller stationary phase packings, and low flow rates in HPLC separations may lead to improved LC/MS applications for pesticides.

3.2.4 Signal Suppression Effect

Another drawback in LC/MS is the signal suppression effect that is prevalent when an analyte co-elutes with a matrix component. MS detection can isolate the analyte from the co-eluting peak through the proper choice of mass(es), but the quantitation can be significantly affected by a reduction in the ionization efficiency of the analyte prior to MS detection. Unlike the matrix enhancement effect in GC, which can lead to overestimation of the calculated concentration for affected pesticides, the signal suppression effect in LC/MS leads to lower resulting calculated concentrations. The methods of reduction or control of the effect may be possible through one or more of the following approaches: (1) further cleanup of the extracts; (2) alteration of the separation conditions; (3) utilization of a different ionization technique; (4) addition of deuterated internal standards; (5) use of the method of standard additions;
and (6) use of calibration standards in a blank matrix. Another approach is to correct results for recoveries, but this is not acceptable in many QA protocols, and the results are typically inaccurate when the effect is concentration dependent.

3.2.5 Liquid Chromatography/Tandem Mass Spectrometry

The use of liquid chromatography/tandem mass spectrometry (LC/MS/MS) (or MS²) does not overcome the signal suppression effect in the presence of interferents, but it can be very useful in avoiding interferring masses and reducing the LOD when two peaks co-elute.¹⁵² There are two types of instruments for MS/MS detection, either tandem quadrupole or ion-trap, that each have advantages and disadvantages with respect to each other. Triple-stage quadrupole MS instruments generally have better precision, ability to determine neutral losses (which is useful in making identifications), and higher mass resolution. The ion-trap instruments are generally smaller, cheaper, and provide MS² capability. LC/MS/MS (or MS³) is considered the state-of-the-art approach for many of the modern pesticides and their metabolites, and pesticide manufacturing companies have relied heavily on the use of the LC/MS approaches in the development and analysis of pesticides. As single-analyte methods are developed for pesticide registrations using LC/MS approaches, the application of these techniques in multiclass, MRMs is expected to increase.

3.3 Capillary Electrophoresis

CE is a technique developed in the early 1980s, but it has only recently made its way into pesticide residue applications.¹⁵³–¹⁵⁶ A variety of formats and options for different types of applications are possible in CE, such as micellar electrokinetic chromatography (MEKC), isotachophoresis, capillary gel electrophoresis (CGE), and capillary electrochromatography (CEC), but biochemical and pharmaceutical applications, not pesticide residues, remain the major focus in studies that use CE.¹⁵⁷ The main problem with CE for residue analysis of small molecules has been the low sensitivity of detection in the narrow capillary used in the separation. With the development of extended detection path lengths and special optics, absorbance detection can give reasonably low detection limits with clean samples.¹⁵⁶ However, complex samples can be very difficult to analyze using CE/UV. CE coupled with laser-induced fluorescence detection can provide extraordinarily low LODs¹⁵⁸ but the analytes must be fluorescent with excitation peaks at common laser wavelengths for this approach to work. Derivatization of the analytes with appropriate fluorescent labels may be possible, as is done in biochemical applications, but pesticide analysis has not been such an important application to utilize such an approach.

As in HPLC, the coupling of MS detection with CE has provided an excellent opportunity for more selective analysis, but the much reduced flow rates, small injection volumes, limitations in the types of buffers used, and the need to maintain a large voltage potential along the capillary make CE/MS (capillary electrophoresis/mass spectrometry) more complicated than LC/MS.¹⁵⁵ Furthermore, 1000-fold lower injection volumes in CE lead to higher LODs in CE/MS than in LC/MS. Techniques such as stacking multiple CE injections can increase injection volumes to possibly overcome the sample injection volume limitation in CE.¹⁵³,¹⁵⁶,¹⁵⁷

The main advantages of CE over HPLC relate to the greater number of theoretical plates, reduction in the use of hazardous solvents, lack of waste, utility in sample limited applications, and general capability for lower LODs with UV and fluorescence detectors (owing to increased resolution in separations and higher signal-to-noise ratio despite the smaller injection volume).²⁵ Unlike the laminar flow profile of chromatographic techniques, plug flow occurs in CE because flow originates along the capillary walls. This generally translates into sharper peaks in CE and better separations.

A common criticism of CE is the lower consistency of migration times for peaks than in HPLC or GC. The effects of matrix components and small differences in ionic strength and pH can have significant effects in the separation. The use of a migration time marker provides a consistent relative migration time that may be used to identify peaks of interest, especially in complex electropherograms.²⁵ As in HPLC, it is often difficult to separate a diverse range of pesticides in CE with the same set of conditions. Hence, CE applications are most likely to be limited to single-class MRMs.¹⁵⁴ CE is most useful for ionic pesticides, but neutral analytes are also possible targets using CEC and MEKC.¹⁵⁹

3.4 Immunochemical Methods

Immunochemical techniques may be useful for fairly rapid and reasonably inexpensive techniques for selected pesticides, or perhaps a selected class of pesticides, but the application of immunochemistry in multiclass, MRMs is limited.¹⁶⁰–¹⁶³ The advantages of the high selectivity, reasonable ease, and relatively low costs are lost when several antibodies are needed to increase the analytical range of the technique. As in nearly all approaches, the selectivity of immunochemical techniques decreases as the analytical range increases, and costs and complexity concomitantly increase. Furthermore, the results of immunoassays are often only semiquantitative, and
separate methods may be needed for quantitation and identification. Furthermore, immunochemical techniques are only useful in aqueous solutions, and pH, ionic strength, matrix components, temperature, and other factors can have large effects in the assays. However, some enzyme-linked immunosorbent assays (ELISAs) are satisfactorily quantitative, rugged, and capable of detecting very low levels (<1 ppb) of targeted pesticides. For example, commercial ELISAs for triazine (e.g., atrazine) and acetanilide (e.g., alachlor) herbicides have performed particularly well in environmental monitoring applications.

In ELISA, relating signal to the concentration is more complicated than traditional means because the calibration plot is inversely proportional and semilogarithmically correlated to the analyte concentration. Also, the signal in ELISA consists of the absorbance of a sample divided by the absorbance from blank sample(s). Furthermore, the analytical range for quantitation in ELISA is generally less than two orders of magnitude. For these reasons, ELISA is not especially useful for quantitative analysis, especially with complex extracts, but its capabilities can be useful in screening applications for individual pesticides. Cleanup of complex extracts has been performed prior to ELISA to improve reliability and quantitation, but in this case it is often less expensive and more reliable to use a traditional method in the laboratory.\(^{164}\)

At this time, ELISA kits are commercially available for approximately 25 pesticides, but several other antibodies have been developed for other pesticides in noncommercial applications. Depending on the format, ELISA kits typically cost $5–10 per assay, which is similar to the cost of materials in typical quantitative and confirmatory multiclass, MRM (Table 6). ELISA tests are often performed in batches and can take from 15 to 120 min, depending on the incubation times for the competitive reaction and enzymatic color change. A batch can consist of 96 samples in the microtiter plate format, but usually fewer samples are analyzed owing to the need for replicates. In the commercial magnetic bead format, replicates are less necessary owing to lower variability, and up to 60 samples may be analyzed in a batch. In some cases, portable ELISA kits can be applied in the field using tube formats with detection by eye or with tube photometers.

Interestingly, many of the disadvantages with ELISA in residue analysis are also advantages, and vice versa, depending on the application. For example, the high selectivity of detection in ELISA is a disadvantage in multiresidue applications. The costs and labor of ELISA increase significantly if more than one kit is to be used to detect a number of pesticides. Also, the use of ELISA can be considered slow and tedious compared with SPME, DSI, or MS screening applications, but it is generally much easier and faster than single-analyte methods. However, the semiquantitative and nonconfirmatory nature of ELISA can potentially lead to a high rate of false positives and false negatives. Even if the results are reliable, a deterministic and/or confirmatory method is often required in the case of a positive response.

The capabilities of immunochemical methods are highly dependent on the antibody. A rugged antibody of high selectivity can provide exceptional results for the targeted analytes in complex extracts that may even contain a small percentage of organic solvents in the aqueous solutions. In other cases, the antibodies may have poor stability and be affected strongly by pH, salt content, temperature, and matrix components. Some antibodies are specific to a single antigen, whereas others are selective to a chemical moiety, and still others can interact rather nonselectively with a variety of compounds. By altering incubation times and antibody-to-sample-to-enzyme–antigen ratios, the sensitivity of analysis can be tailored to achieve very low, or not as low, detection limits.

Investigations of immunochemical or biochemical formats that are potentially faster, more quantitative, easier to perform, less expensive, more rugged, and suitable for a wider range of pesticides than ELISA are being conducted. These approaches involve enzymes, biosensing, flow injection, optical fibers, molecular imprinting, and other methods.\(^{165–167}\) Biosensing methods of analysis that take advantage of modes of action of different pesticides, e.g., cholinesterase inhibition, can be very effective but, unfortunately, current cholinesterase-based detection kits for OPs and carbamates are not sensitive enough for most monitoring applications.\(^{168}\) Sensitive, specific, rapid, and reliable screening assays based on immunochemical or biosensing concepts are commercially available and widely used in clinical and veterinary testing applications. However, the analysis of pesticides has not warranted such attention from manufacturers, mainly owing to the need for multiclass, multi-residue results rather than those for specific analytes. Unless these type of techniques for pesticide residues become commercially available, they will only rarely be used because the process to prepare the biosensing or immunological materials is often expensive, time-consuming, and complicated. Screening methods are often desired to increase the number of monitored samples, but fast and accurate analytical methods other than biosensing or immunological techniques are more likely to be developed for a wide range of pesticides to meet the analytical goals.

4 CONCLUSIONS

Owing to the introduction of a number of sophisticated technologies and instruments, tremendous improvements

a D = defoliant; F = fungicide; H = herbicide; I = insecticide/acaricide.
in the ability to analyze multiple pesticides for multiple classes in a variety of sample matrices have occurred in recent years. A growing number of techniques are available to the analytical chemist, and many strategies are possible to meet the purpose of analyses. In general, the use of the fewest analytical steps that provides reliable results in a rugged approach serves as the best overall approach to determining pesticide residues in food, environmental, and other types of samples. An inherent difficulty in multiclass, multiresidue analysis is that as the range of analytes increases, the overall selectivity of the sample preparation decreases. Therefore, trade-offs and compromises must often be made in obtaining high recoveries of a wide range of analytes while minimizing time, effort, and cost of the procedure(s).

Ultimately, these fundamental and practical aspects may limit the ability of the strategy to meet the needs of the analysis. As this article describes, a host of strategies are available to the chemist, but practical concerns in the laboratory, such as time, budgets, available instruments, and personnel, limit the amount of effort and resources that can be devoted to the analysis. A clearly superior, efficient and all-encompassing strategy has yet to be devised, which has made method development in multiclass, multiresidue analysis of pesticides an active area of study. The number of different pesticides and sample types leads to unique challenges in the determination of multiclass, multiresidue pesticides that few other areas of analysis match.

Finally, for reference, a list of a wide range of pesticides, with CAS numbers, uses, classes and solubilities in water are given in Table 10.

Organochlorine (OC) pesticides is a general term for a broad class of compounds including some well-known compounds such as dichlorodiphenyltrichloroethane (DDT), lindane, dieldrin, endrin, heptachlor epoxide (HEPO), endosulfan, and chlordane. OC pesticides are the first class of compounds introduced in agricultural and civil uses to counteract noxious insects and insect-borne diseases. In general they are lipophilic compounds with noticeable chemical and environmental stability. Although most OC pesticides have been progressively restricted and then banned in the 1970s in most industrialized countries, a widespread environmental pollution has resulted from their use in agriculture and civil uses.

Pyrethrins are natural insecticidal compounds found in the extract of pyrethrum flowers. Also, a number of pesticides have been synthesized that share the biologically relevant chemical moiety with the pyrethrins and are referred to as pyrethroids (PYR). These compounds possess equal or better biological activity and better chemical stability that allow their use in agriculture, husbandry, and civil applications. Both OC and PYR pesticides can occur in fruits and vegetables as well as in food of animal origin and environment. The levels can be different as a result of direct application or indirect contamination. Such different matrices and levels of contamination require different analytical approaches and resources.

A review is presented of the array of the analytical techniques most frequently applied for the extraction, cleanup and identification/determination. Extraction techniques include solvent extraction, supercritical fluid extraction (SFE), solid-phase extraction (SPE), and solid-phase microextraction (SPME). Solvent extraction is carried out in different ways depending on the type of matrix (fatty and nonfatty samples, soil, sediments, and water), such as Soxhlet, liquid–liquid extraction (LLE), pressurized liquid extraction (PLE), and matrix solid-phase dispersion (MSPD).

Different cleanup techniques are presented that can be applied to fatty and nonfatty samples. They include liquid–liquid partitioning (LLP), size-exclusion chromatography (SEC), sweep codistillation and assisted distillation, column adsorption chromatography, chromatography on SPE cartridges, high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC) and degradative cleanup. The techniques are presented as modular steps that can be arranged in different ways to cope with cleanup requirements posed by different sample composition and different selectivity/sensitivity of the identification/determinative techniques. The performances of the cleanup steps are discussed in terms of matrix removal.
and amount of sample that can be handled. Also the possibilities of linking different steps and the chance for automation of the cleanup process are indicated. Some environmental pollutants, such as polychlorinated biphenyl (PCB), have similar analytical behavior to some OC pesticides and can occur in the same environmental matrices. Some cleanup steps useful for the group separation of PCB and OC pesticides are presented. The techniques for identification and determination include gas chromatography (GC) with selective detectors, HPLC, and their combination with mass spectrometry (MS). The importance of the combination of responses from different analytical techniques to obtain reliable identification at trace levels is underlined.

1 INTRODUCTION

Pesticides are chemicals intended to combat unwanted or noxious organisms in a variety of matrices in different fields of application such as agriculture, husbandry, civil, and industrial premises. Pesticides belong to a wide range of chemical classes and are divided into categories of organisms they counteract (insecticides for insects, acaricides for mites, nematocides for nematodes, fungicides for fungi, and herbicides for weeds).

The modern history of pesticides dates back to World War II when for the first time the insecticidal properties of DDT were recognized. DDT was first introduced on a large scale to fight fleas, lice, flies, and mosquitoes and reduce the spread of insect-borne diseases such as typhus (body lice), malaria, and yellow fever (mosquitoes) and plague (flies).1

The first synthetic pesticides belong to the broad class of OC pesticides which includes the chloro diphenyl aliphatics (DDT, dichlorodiphenyl dichloroethane (DDD), methoxychlor), the hexachlorocyclohexanes (HCHs), chlorocyclodienes (heptachlor, aldrin, chlordane, dieldrin, endrin, and mirex).2,3 Table 1 gives chemical formulas of the cited OC pesticides.

Pesticides as well as other chemicals released into the environment tend to distribute into different compartments and their distance from the site of application depends on the chemico-physical properties and chemical stability of the pesticide and the environmental conditions. Pesticide degradation processes involve biotic (vegetable and animal metabolism, microorganism and enzymes) and abiotic (oxidation, hydrolysis, breakdown by heat and ultraviolet (UV) light) transformations. OC pesticides are generally recognized as highly stable lipophilic compounds. Thus, they have a tendency for bioaccumulation in fatty tissues of animals along the food chain.

1.1 Dichlorodiphenyltrichloroethane and Related Compounds

DDT belongs to the class of diphenyl aliphatics, which consists of an aliphatic chain with two phenyl rings attached. DDT was produced as a technical material comprising the \( p,p' \)-DDT and \( o,o' \)-DDT isomers and the related compounds \( p,p' \)-DDD (TDE), \( o,o' \)-DDD (TDE), \( p,p' \)-DDE (dichlorodiphenyldichloroethylene) and \( o,p' \)-DDE. A typical sample of technical DDT comprised 77.1% \( p,p' \)-DDT, 14.9% \( o,p' \)-DDT, 0.3% \( p,p' \)-DDD, 0.1% \( o,p' \)-DDD, 4.0% \( p,p' \)-DDE, 0.1% \( o,p' \)-DDE, with the remaining 3.5% being unidentified compounds. Besides being present in the technical product, some of these compounds are also metabolites of DDT. Two main pathways of DDT metabolism exist in mammals, i.e. dehydrochlorination to DDE and stepwise conversion to DDA (di(\( p \)-chlorophenyl)acetic acid) via DDD. DDE and DDD are also formed in insects, soil, and to a lesser extent in vegetables. In many industrialized countries DDT has been progressively restricted and then banned in the 1970s. However, it is still used in some countries to control malaria. Therefore, from an analytical perspective, the determination of the complex of isomers and metabolites is important at residue level.4 Related pesticides include TDE (DDD) (which has not been used to a great extent), methoxychlor and dicofol.

Methoxychlor is an insecticide. Owing to the presence of two methoxy groups at para positions on the phenyl ring, methoxychlor is less environmentally stable than DDT and it is degraded via \( O \)-dealkylation and dehydrochlorination. Thus, methoxychlor has a poor tendency to bioaccumulation.

Dicofol is a non-systemic acaricide used to control phytophagus mites. It is degraded in plants and animals to dichlorobenzophenone (DCBP).5 Its synthesis and degradative pathways have some steps in common with DDT and its metabolites.6

1.2 Hexachlorocyclohexanes

HCH is made by chlorination of benzene, which results in the formation of five isomers differing in the spatial position of chlorine atoms and named using the Greek letters \( \alpha, \beta, \gamma, \delta, \) and \( \epsilon \). Only the \( \gamma \)-isomer (lindane) has insecticidal activity and is present at about 14–15% in the technical material, which also typically contains 65–70% \( \alpha \)-HCH, 7–10% \( \beta \)-HCH, and ca. 10% of \( \delta \) and \( \epsilon \)-isomers. Technical material was initially used for insect control, but after recognizing its undesirable characteristics (musty odor and flavor), only lindane continues to be used for a limited type of application, such as seed treatment, in industrialized countries.44 However, the other isomers are more persistent than lindane and

may still be found at residue levels in the environment and animal tissues.

### 1.3 Chlorocyclodienes

The main compounds in this class are chlordane, aldrin and dieldrin, heptachlor, endrin, mirex, α-endosulfan and β-endosulfan. They are persistent insecticides which may be used in some countries mostly in soil applications. Because of their persistence, the use of chlorocyclodienes on crops, except endosulfan, was restricted and/or banned between 1975 and 1980.

Technical endosulfan consists of a mixture of α- and β-isomers in the approximate ratio of 70:30 (w/w). Endosulfan is less persistent than the other chlorocyclodienes, and oxidizes into endosulfan sulfate. Dieldrin, besides being an insecticide per se, is the oxidation product of aldrin. Heptachlor and chlordane also oxidize into heptachlorepoxide and oxychlordane, respectively. Other compounds such as trans-nonachlor are present at residue level as byproducts of the synthesis of heptachlor, while hexachlorobutadiene is a common byproduct of the chlorination process. Chlordane has two isomers, α and γ, and is also present in technical heptachlor.¹⁻⁴

### 1.4 Camphechlor

Camphechlor (toxaphene) is manufactured from the chlorination of camphene and consists of more than

¹⁻⁴ Source references are omitted for brevity. Additional information can be found in various scientific journals and reports dealing with environmental chemistry and toxicology.
177 polychlorinated derivatives, most of them being isomeric C_{17}, C_{18}, and C_{19} bornanes. Toxaphene is an insecticide mainly used in cotton fields and for the control of termites. Toxaphene is persistent in soil but is fairly easily metabolized by mammals and birds, and does not accumulate in body fat to such a great extent as do DDT, HCH, or chlordane. Despite its low toxicity to mammals, insects, and birds, fishes are highly susceptible to toxaphene poisoning.\(^1\)\(^-\)\(^4\)

These compounds as well as PCBs occur in the environment as complex mixtures at trace level and require special analytical methodologies which are not specifically dealt with in this article.\(^7\)

1.5 Other Relevant Organochlorinated Compounds

Hexachlorobenzene (HCB) is actually a fungicide used in the past in the treatment of stored grains. It is highly lipophilic and is found ubiquitously in environmental fatty matrices.\(^4\) It is also found as a contaminant of quintozene (pentachloronitrobenzene), a fungicide used in soil treatments.\(^4\)

PCBs are materials used mostly in the past years in industrial applications such as dielectrics, heat exchangers, and brake and hydraulic fluids. Accidental release and/or inadequate waste disposal has lead to widespread environmental pollution. Because of their stability and lipophilicity they pose almost the same problems as OC insecticides and behave similarly in most analytical procedures.\(^3\)

A number of other polychlorinated compounds are of concern in environmental pollution including polychloronaphthalenes, polychloroterphenyls,\(^4\) polychlorodibenzodioxins and polychlorodibenzofurans.\(^4\)

1.6 Pyrethrins and Pyrethroid Insecticides

With the development of pesticide chemistry other classes of insecticides have been introduced. These include organophosphates and carbamates that are generally much more acutely toxic to vertebrates than OCs insecticides. They are less chemically stable and persistent than OCs and do not give rise to environmental bioaccumulation.

Pyrethrins are insecticidally active compounds present in the extract of pyrethrum flowers. Pyrethrin extract contains six related compounds, but the analysis is focused on the main and more active compounds, pyrethrins I and II, which are present at about 33–35% each in the extract. Pyrethrins are normally used in formulations containing the synergist piperonyl butoxide, which is also of analytical interest. Pyrethrins have rapid knock-down activities on insects, but are not suitable for agricultural uses because of their instability in sunlight.

One of the last classes of insecticides introduced is PYR. In the course of several years a number of compounds have been synthesized that possess some of the characteristics of pyrethrins combined with sufficient environmental stability and residual activity for agricultural uses. Most PYR pesticides were first introduced on the market as a mixture of stereoisomers resulting from the synthesis. Individual enantiomers have different biological activity and are increasingly used in formulations. Also the degradation of the enantiomers is different in the environment and at residue level.\(^4\)

Some of the above-mentioned compounds are shown in Table 2.\(^5\)

Depending on the chemical structure, stability, chemophysical properties, environmental conditions, and time and mode of application, pesticides used in agriculture and in civil applications or sanitary programs may give rise to residues in crops at harvesting and/or in different environmental matrices. In general terms, residues occur as high as a few micrograms per kilogram (ppm, parts per million) for pesticides used in agriculture, but indirect, long-lasting contamination by persistent compounds such as OC pesticides may be found ubiquitously at microgram per kilogram (ppb, parts per billion; 1 in 10^\(^9\)), nanogram per kilogram (ppt, parts per trillion; 1 in 10^\(^12\)), and femtogram per kilogram (ppq, parts per quadrillion; 1 in 10^\(^15\)), levels.

1.7 Analytical Methods

It is obvious that analytical determinations at such widely different levels pose different difficulties. However, a tremendous number of publications have been devoted to the development of methods for pesticide residue analysis in foods and environmental matrices.

The determination of OC and PYR pesticides follows some common approaches applicable in general to the determination of trace amounts of organic compounds in complex matrices.\(^8\)\(^-\)\(^17\)

2 SAMPLE PREPARATION

The analytical method is generally considered to begin with sample preparation. Sample preparation involves the isolation of the sample portions that are indicated in the definition of the legal limit, or maximum residue level (MRL), for foods, or the portion of the substrate for which the analysis is intended. Afterwards, this sample portion (analytical sample) is taken for analysis. The analytical sample is often larger than the amount strictly needed for the analysis from a technical point of view, but the larger size may be more convenient to work with or lead to a more representative sampling procedure. Otherwise,

a procedure should be applied to derive the aliquot of analysis, i.e. the portion of the sample brought to the extraction step. In order to have a representative aliquot, the laboratory/analytical sample should be thoroughly comminuted (chopped, or milled) and mixed to obtain an homogeneous material. If possible, the entire laboratory/analytical sample should be processed. If this is not possible, a reducing procedure such as quartering (division into quarters and taking opposite corners), is applied. When applying a quartering procedure to large
units, they should be divided according to their symmetry, taking into account that the distribution of pesticide residues may not be even.

The differences in the sample structure may also require different procedures and mechanical equipment to get a homogeneous analytical sample. Most biological samples are better comminuted while frozen. For this purpose, liquid nitrogen can be useful (e.g. cryogenic milling). The addition of dry ice keeps the sample frozen and increases the mechanical shredding. Comminution at low temperature is also recommended to avoid decomposition of heat-labile compounds. Lyophilization is sometimes used to remove the water from the samples in order to increase the aliquot taken for the analysis and/or to facilitate the extraction, but may give rise to losses by evaporation.

The action of chopping, cutting, blending, or milling machines should be evaluated with representative crops or goods to be analyzed in order to check the performance with samples of different texture and to assess the minimum size of the aliquot of analysis that can be still considered representative of the laboratory sample. Homogenization is particularly important when using methods that require a small aliquot for analysis. The variance of the sample preparation adds to the variance of the analytical procedure and can contribute significantly to the overall quality (accuracy and precision) of the results.

3 EXTRACTION

3.1 Nonfatty Samples

Extraction is the step aimed at separating the analytes from the insoluble part of the matrix and transferring them into a solvent amenable to the subsequent steps of the method. The use of different solvents and solvent mixtures has been reported, depending on the analytes and matrices. In multisolute methods, the extraction solvent should extract polar and apolar analytes because it is of interest to extract as many analytes as possible. Increasing the polarity of the solvent improves the extraction of polar analytes, but generally increases the amount of coextractives.

For nonfatty samples (commonly those containing less than 2–5% fat), water-miscible solvents such as acetonitrile, acetone, ethanol, and methanol and polar, partially water-miscible solvents such as ethyl acetate or polar, partially water-miscible solvents such as acetonitrile and ethanol, have been extensively used for the extraction of pesticides. Methanol and ethanol are preferred because they are less toxic and expensive, and have a lower boiling point. Methanol also has been less frequently used because of its toxicity, although it is indicated as a better extracting solvent for some categories of pesticides such as carbamates, but does not work as well for nonpolar analytes.

Low-moisture foods, such as grains, are better extracted with solvent mixtures such as acetonitrile–water (65:35 v/v), acetone–methanol (1:1 v/v), acetone–water (8:1 v/v). Water helps to swell the dried material, thus allowing a better penetration of the water-miscible solvent. Both water and methanol generally improve the extraction by reducing the adsorption of the analytes on insoluble material and container surface, but this is not necessarily the case for nonpolar compounds.

The process of extraction is carried out by homogenizing a portion of the previously comminuted sample in high-speed blenders/homogenizers. The solvent is separated by filtration after the addition of filter aids, such as diatomaceous materials, or after centrifugation. In the extraction with ethyl acetate or other solvents immiscible with water, anhydrous sodium sulfate is added to remove the water.

3.2 Fatty Samples

Most methods for fatty foods have been developed for PYR, OC and organophosphorus (OP) pesticides due to the lipophilic nature of these pesticides. The most common approach entails thorough extraction of the fat to completely extract lipophilic pesticides. Therefore, extraction procedures for pesticides follow the classical methods for the determination of total fat content. For instance, animal tissues and dairy products are thoroughly mixed with anhydrous sodium sulfate to remove water and help disintegrate the tissues. Then the mixture is extracted with a Soxhlet apparatus with petroleum ether, or n-hexane–acetone (59:41 v/v) mixture, or n-hexane–dichloromethane (DCM) (4:1 v/v), or blended at high speed. The solvent is evaporated and the raw fatty extract is obtained after evaporation of the extracting solvent, or after partition into n-hexane and evaporation.

In some cases, an extraction step may not be needed. For example, butter fat is obtained from butter by melting and filtering to remove the solids. Fats and oils can be subjected directly to one of the cleanup steps.

Milk and dairy products are usually extracted with the total fat extraction approach using petroleum ether–diethyl ether (1:1 v/v), after the addition of denaturing agents such as potassium oxalate, which solubilizes the proteins, and methanol or ethanol, that avoids the formation of emulsions. Also human serum has been
extracted with petroleum ether–diethyl ether in the presence of methanol.\(^{(44)}\) Extraction of total milk fat and lipophilic pesticides is also possible with a combination of apolar and polar solvents, such as \(n\)-hexane–acetone (50:50 v/v)\(^{(46,45)}\) ethyl acetate–ethanol (95:5 v/v),\(^{(46)}\) or ethyl acetate–acetone–methanol (2:4:4 by vol.),\(^{(47)}\) or with acetone alone\(^{(48)}\) or acetonitrile.\(^{(49)}\)

Eggs have been extracted according to the total fat extraction approach by drying with anhydrous sodium sulfate and blending with a mixture of \(n\)-hexane–acetonitrile (2:1 v/v),\(^{(50)}\) which has been proved to extract more fat than extraction with petroleum ether–diethyl ether.\(^{(8)}\)

In a different approach, fatty tissues can be extracted with acetonitrile.\(^{(49,51)}\) In this case, a selective extraction of pesticide residues including OC and PYR pesticides is accomplished. Pesticide residues are extracted efficiently while most of the fatty matrix is left, with great advantages in the subsequent cleanup process.

Also, for milk a selective extraction of pesticide residues is possible by mixing the milk with acetonitrile and ethanol and partitioning into \(n\)-hexane,\(^{(52)}\) or by mixing with acetonitrile and passing the resulting solution through an SPE C\(_{18}\) cartridge (SPE with octadecyl-silica), which traps the OC pesticides.\(^{(49)}\) In both cases OC pesticides are recovered efficiently accompanied by a substantially lower amount of fat than in the conventional total fat extraction approach. This amount of fat allows a small-scale cleanup with saving of solvents, adsorbents, and time.

The above-mentioned extraction processes are carried out by putting into intimate contact the sample and the solvent. Mechanical blenders/homogenizers are most commonly used, and ultrasound is often applied to this end. The extracting solvent is separated by centrifugation or by filtration through paper or glass fiber disks, often after the addition of filtration aids, usually diatomaceous earth. Not infrequently emulsions and/or jelly suspensions are formed that complicate the separation of the extracting solvent. Addition of small amounts of polar solvents or saline solution and centrifugation are often useful to overcome this problem.

### 3.3 Matrix Solid-phase Dispersion Extraction

In a different approach, MSPD (sometimes referred to as on-column extraction), the intimate contact between the sample and the solvent is realized by thoroughly mixing the finely divided sample with solid sorbents. Common sorbents used in MSPD include diatomaceous earth material (Celite, Extrelut, Hydromatrix), synthetic magnesium silicate (Florisil), or silica. The sample plus material mixture is packed in a column and eluted with the solvent under gravity at ambient temperature. This column extraction has been reported for vegetables mixed with Extrelut (10 g vegetable + 12 g Extrelut eluted with 100 mL DCM),\(^{(53,54)}\) or Hydromatrix (25 g sample + 25 g Hydromatrix eluted with 250 mL ethyl acetate),\(^{(55)}\) or Florisil (5 g vegetable + 8 g Florisil eluted with 70 mL DCM–acetone (9:1 v/v) or ethyl acetate).\(^{(56)}\) In a similar application 5 g vegetable was mixed with 8 g Florisil and extracted on-column with 60 mL \(n\)-hexane–acetone (9:1 v/v).\(^{(57)}\)

Milk and dairy products, and eggs, were mixed with silica gel (5 g sample + 15 g silica gel), while fish tissue was mixed with sodium sulfate and clean sand (1 g fish + 3 g sea-sand and 10 g sodium sulfate). In both cases, the sample mixture was loaded onto the top of a 10% water-deactivated silica gel column, and the bilayer column eluted overnight with 150 mL petroleum ether–DCM (80:20 v/v).\(^{(58,59)}\) In these applications, the on-column extraction performs both the extraction and cleanup, because the extract is passed in-line through the silica gel adsorption column. In similar applications, OC pesticides can be extracted from fish tissue homogeneously mixed with C\(_{18}\) powder (0.5 g tissue + 2 g C\(_{18}\)). The mixture is put on the top of a small column of Florisil. The bilayer column is eluted with 8 mL acetonitrile.\(^{(60–62)}\) The MSPD takes advantage of the sample shredding generated while grinding the sample with irregularly shaped solid particles, and lipid-retaining ability of a lipophilic support (C\(_{18}\)). Thus, the bilayer column carries out both a selective extraction and a cleanup step (Florisil) in a single process. MSPD uses mild conditions for extraction (ambient temperature and pressure) and has been found useful in avoiding the degradation of dicofol to DCBP during Soxhlet extraction of avian eggs.\(^{(63)}\) Preferential flow and sample that has not been carefully mixed are the principal drawbacks that can result in poor recovery.

Also the selective extraction of OC, OP, and PYR pesticides from milk and milk powder can be carried out by loading a mixture of milk or reconstituted milk with acetonitrile and ethanol (5 mL of a mixture of 10 mL milk + 5 mL acetonitrile and 1 mL ethanol) into a cartridge filled with Hydromatrix. The OC, OP, PYR pesticides are selectively recovered from the material by eluting the cartridge with 20 mL \(n\)-hexane saturated with acetonitrile and ethanol. Milk fat is carried over to a limited extent (ca. 5 mg mL\(^{-1}\) of milk) compared to the nominal fat content (ca. 180 mg mL\(^{-1}\)) of the whole milk and the subsequent cleanup can be miniaturized to save solvents, reagents, and time.\(^{(64–66)}\)

### 3.4 Soil and Sediments

OC pesticides are extracted from soil by shaking the sample overnight with \(n\)-hexane–acetone (1:1 v/v) (typically 10 g with 100 mL) after the addition of ammonium chloride solution.\(^{(8)}\) Fenpropatrin and fluvalinate have
been extracted from soil mixed with charcoal (25 g soil + 0.5 g charcoal) by column extraction with 100 mL n-hexane–acetone (9 : 1 v/v).\(^{167}\) Lower solvent/solid ratio (20 mL/10 g) with methanol and sonication for 15 min proved more efficient and rapid than the conventional shaking method or Soxhlet extraction in extracting some PYR pesticides from soil.\(^{68}\) Sonication provides a more efficient contact between the solid and the solvent, but longer sonication caused a decrease in recovery, probably due to some degradation of the compounds. Sonication for 5 min and high solvent/solid ratio (150 + 100 mL/20 g) were found necessary in a multiresidue method for extracting 120 pesticides, including OC and PYR, from high organic matter soil.\(^{69}\)

To improve the efficiency of the extraction, heat can be supplied by microwave energy. The principle involves heating both the solvent and the matrix by wave–matter interaction. The process is carried out in a special microwave oven (typical conditions: 10 g soil and 30 mL n-hexane–acetone (1 : 1 v/v) at 110 °C for 10 min). As a result both temperature and pressure are increased and there is a chance of degradation of sensitive compounds by exposure to high temperature and catalytic sites in the soil.\(^{70–72}\)

### 3.5 Water

Water or wine is extracted by classical LLE in a separatory funnel by shaking it with an immiscible solvent such as DCM.\(^{73,74}\) To increase the sensitivity and avoid concentration of the extracting solvent, OC and PYR pesticides can be extracted from water with a small volume of n-hexane (1 mL). After the extraction, the hexane layer is raised up to the bottle neck of the separatory funnel by raising the communicating vessel filled with deionized water.\(^{75}\)

Water and water-diluted liquid samples can be passed through lipophilic SPE cartridges to extract OC and PYR pesticides. The most widely used sorbents are C\(_{18}\), polystyrene–divinylbenzene (PS–DVB), and graphitized carbon.\(^{76}\) A typical application includes extraction of 1 L of water,\(^{77}\) or 50 mL of wine diluted with 200 mL of water,\(^{79}\) both with a 500-mg C\(_{18}\) cartridge. Centrifuged human plasma (1 mL diluted with 3 mL water) was passed through a 100 mg C\(_{18}\) cartridge.\(^{80}\)

Filter disks of polytetrafluoroethylene with C\(_{18}\) particles embedded have been used to speed up the extraction of large samples (about 20 min with a 47 mm diameter disk compared to about 1–2 h with a C\(_{18}\) cartridge, for a 1 L sample).\(^{81,82}\) Automated SPE can be combined with large-volume GC introduction techniques for the automated extraction and determination of PYR pesticides in water.\(^{76,83}\)

SPME is a solventless extraction technique in which the analytes are extracted directly from the aqueous samples onto a polymeric stationary phase that coats a fused silica fiber. The fiber is dipped into the aqueous sample under stirring (in certain applications the fiber is exposed to the headspace above the sample) allowing the adsorption of the analytes, according to their partition coefficient, into the polymeric phase. The analytes are thermally desorbed directly into a gas chromatograph by inserting the fiber into the hot injector. After a few minutes the fiber is withdrawn and reused for subsequent analysis. Different fiber coatings provide different adsorption properties for different compounds. The most commonly used fiber coating is poly(dimethylsiloxane), which is relatively nonpolar, and useful for nonpolar compounds such as OC pesticides. For more polar analytes a polyacrylate coating has been used. Fiber coating thickness is in the range 15–150 µm. Temperature and time of adsorption and desorption have to be optimized in relation to the sample characteristics and analytes. The typical temperature for adsorption is from ambient to 45 °C for 20–90 min, while the desorption temperature is in the range 250–260 °C for a few minutes. Elimination of solvents, easy automation, and the possibility of on-site sampling are among the advantages of SPME.\(^{84–90}\) On-line solvent desorption into a liquid chromatographic column has been developed for compounds that require HPLC for analysis.\(^{95}\)

#### 3.6 Pressurized Liquid Extraction

PLE is a semiautomated technique in which extraction can be enhanced and speeded up, and solvent consumption reduced, by increasing temperature and pressure. As in MSPD, the sample is mixed and dispersed with macroporous materials such as Hydromatrix and/or anhydrous sodium sulfate. This acts to disperse the matrix, improve homogeneity, and ease flow of solvent through the sample. The mixture is loaded into a closed vessel through which the solvent is passed under increased temperature and pressure. The solvents are those normally used for conventional extraction procedures. The technique basically uses a static extraction step of 5 min at elevated temperature (50–200 °C) and pressure (7–20 MPa) that enhances solubilization and desorption of the analytes from the matrix, followed by a washing of the cell with fresh solvent for total recovery of the extracted analytes.\(^{91}\) Dried materials such as soil are mixed with anhydrous sodium sulfate in about a 1 : 1 w/w ratio and extracted with n-hexane–acetone (1 : 1 v/v)\(^{92}\) or DCM for 5 min static extraction at 100 °C and 13.8 MPa under conditions similar to those of EPA Method 3545.\(^{94}\) Other pesticides have been extracted from soil mixed with Hydromatrix (1 : 0.1 w/w) by acetonitrile under the same conditions.\(^{95}\) PLE gives excellent recoveries in a short time and has been compared favorably with Soxhlet, sonication, microwave-assisted extraction (MAE) and
SFE. Vegetable samples were mixed with Hydromatrix or Extrelut in a 1:1 w/w ratio and extracted with ethyl acetate at temperatures of 50–100 °C and a pressure of 143.8 MPa for 5 min. Typical sample sizes are 5–10 g mixed with inert material in a 11- or 22-mL vessel eluted with 20–40 mL. Lower temperature reduces the amount of water in the extract that has to be removed by anhydrous sodium sulfate. Furthermore, under increased temperature and pressure there is a chance of degradation as in MAE in a closed vessel. Instruments are commercially available under the trade names ASE, ESE, and PSE for processing multiple samples.

3.7 Supercritical Fluid Extraction

In SFE sample preparation is quite similar to that inPLE; the sample is extracted by passing a supercritical fluid (typically CO$_2$) through the cell. In some cases, a small amount of polar solvent modifiers (e.g. methanol, ethanol, or acetonitrile) is added to improve extraction, depending on the analytes and matrix. SFE is a relatively selective extraction technique which has been applied to the extraction of pesticide residues from vegetables, soils, and fatty tissues with a reduced removal of coextractives. However, expensive apparatus and selection of appropriate conditions are needed, and, in the case of fatty foods, further cleanup for OC pesticides is needed prior to determination. Typical sample sizes are 2–5 g in 10-mL vessels.

Fatty and nonfatty samples are mixed with Hydromatrix in a 1:1 to 1:2 w/w ratio to retain the water that would be extracted by supercritical CO$_2$. Typical conditions are: 2 min static extraction followed by dynamic extraction at 20–32 MPa and 40–60 °C with CO$_2$ flow rates in the range 1.6–3 mL min$^{-1}$ for six extraction vessel volumes. The extract is collected in a trap filled with chromatographic material such as C$_{18}$, alumina, Florisil or glass beads usually at ambient or subambient temperature. For lyophilized fish powder the trap was Florisil. Inclusion of alumina in the extraction vessel served to reduce the extraction of fat from lyophilized fish. However, while PCBs were satisfactorily recovered, some degradation of DDT was observed. A cartridge of chromatographic material such as silica gel, aminopropyl silica gel, or Florisil connected in-line downstream to the extraction vessel adequately separated PCBs from lipids when eluted with supercritical CO$_2$. In another application to fatty samples, the extracted material is cleaned up by passing the supercritical fluid in-line through a preparative column of methyl silica (C-1) connected downstream to the extraction vessel. A multivessel SFE instrument has been evaluated for the simultaneous extraction of up to six fatty samples.

4 CLEANUP

Cleanup is the part of the analytical method aimed at selectively removing as much coextracted material as possible before the identification/determination step. The amount of coextracted material that needs to be removed is often dictated by the selectivity, sensitivity, and robustness of the determinative technique and by the concentrations at which the analytes are measured. Therefore, cleanup may consist of a single step or a combination of steps, some of which are essential and some of which can be omitted depending on the type of sample, extraction method, and the technique and instrumentation used for identification/determination. In some instances, the raw extract can be analyzed without cleanup. In any case, cleanup is a compromise involving efficiency, time, and cost. Although published methods report specific sequences of cleanup procedures (blocks), most cleanup steps can be arranged in desired sequences to separate particular types of chemicals, or deal with particular problems.

Simple operations can be used to link different cleanup blocks by tailoring the approach to most conveniently take into account the amount of coextracted material and type of solvent each block can accept. Solvent exchange, i.e. concentration to dryness and redissolution in a suitable solvent, is the most common operation between different steps of the analytical method.

Cleanup includes an array of chemical separations aimed at removing unwanted coextractives by taking advantage of physico-chemical differences in polarity, dissociation constants, volatility, molecular size, chemical stability, solubility in different solvents, and other factors.

4.1 Liquid–Liquid Partitioning

4.1.1 Nonfatty Samples

When fruits, vegetables, and other nonfatty samples are extracted with water-miscible solvents such as acetone, acetonitrile, and methanol the usual subsequent step in the approach involves the dilution of the extract with saline solution and the extraction of pesticide residues from the diluted raw extract with an immiscible solvent or solvent mixture by shaking in a separatory funnel. Hydrophilic coextractives remain preferentially in the watery phase, while nonpolar and semipolar pesticide residues partition into a solvent that is more easily evaporated and amenable to the subsequent cleanup steps. The more polar the extracting solvent, the wider the range of the analytes that can be recovered, but the amount of the coextractives generally increases. For recovery of low to medium polarity analytes, such as OC and PYR pesticides from aqueous acetone
or aqueous acetonitrile, a relatively nonpolar solvent such as petroleum ether achieves high recovery of the analytes and fewer nonfatty matrix components partition into the organic phase.\(^{6,9,27,37,106,107}\) DCM, or DCM–petroleum ether (1:1 v/v), are more appropriate to recover pesticides with a wider polarity range.\(^{22–26,38}\) With acetonite as the extracting solvent of fruits and vegetables, after the partition into DCM about 0.5–2 mg of coextractives per gram of sample remain in the extract. Adjusting the pH to 7, generally with phosphate buffer, in the extraction or partition step prevents the partitioning of endogenous acids and is useful to reduce coextractives from fruits and vegetables, especially citrus fruits.\(^{21}\) For vegetable samples extracted with methanol or ethanol, the analytes are usually partitioned into toluene.\(^{30–32}\)

The LLP procedure is normally carried out in a separatory funnel, in which the solvent of higher density forms the lower layer. Only one separatory funnel is needed to perform multiple extractions, while solvents less dense than water (e.g. ethyl acetate) require multiple separatory funnels to perform multiple extractions. Emulsions (especially with sugar- and pectin-rich vegetables), manual labor, high glassware needs, and lengthy operation are the main drawbacks of traditional LLP.

Other ways of getting rid of the aqueous phase include the “salting out” process to separate the acetonitrile.\(^{20,21}\) or the addition of water-immiscible solvents, such as DCM–n-hexane (1:1 v/v) or ethyl acetate, or a mixture thereof, to separate a mixture of solvents containing the analytes.\(^{15,108}\) This type of partition leads to the separation of polar solvent mixtures, so that OC, PYR, and more polar compounds can be recovered. The operation is normally carried out in the same vessel used for the extraction. The volume of solvent separated should be recorded and taken into account in the calculation of the results.

Instead of the labor- and time-consuming operation using separatory funnels, the same type of partition can be advantageously carried out by absorbing a portion of the aqueous acetonite extract into cartridges filled with macroporous diatomaceous material.\(^{109}\) The material acts as a support where the partition takes place. Then, acetonite is partially evaporated by an upward stream of nitrogen, and the cartridge is eluted with petroleum ether, DCM, or mixtures thereof. With different combinations of nitrogen flow and time, different amounts of acetonite remain on the columns, and, combined with the selected solvent, the polarity range of the compounds that can be recovered is controlled. This also provides some control over the amount of coextractives removed from the cartridge. Low to medium polarity compounds, such as OC and PYR pesticides, can be recovered by reducing the acetonite content to ca. 50% of the original (2:1 acetonite–sample to 1:1 acetonite–sample) and eluting with low polarity solvents, such as petroleum ether or petroleum ether–DCM (75:25 v/v).\(^{109}\) Unlike using the separatory funnel, this approach uses disposable items, is simple and straightforward, and avoids emulsions.

Another way of recovering pesticide residues from aqueous acetonite or aqueous acetonitrile is by SPE. The solution resulting from the extraction is diluted with water to bring the solvent concentration down to ca. 5–10% and, then, is passed through a lipophilic cartridge, such as PS–DVB\(^{29}\) or C\(_{18}\)\(^{110}\) or a C\(_{18}\) extraction disk.\(^{111}\) Pesticide residues are retained in the solid phase while the aqueous phase is discarded. Pesticide residues are eluted from the cartridge with a solvent, for instance, ethyl acetate\(^{29}\) or acetonite–ethyl acetate (1:1 v/v).\(^{111}\)

### 4.1.2 Fatty Samples

The extraction of fatty samples, which can include both plant (e.g. avocado) or animal tissues, commonly results in significant amounts of coextracted lipidic material. The separation of pesticide residues from the bulk of the coextracted fat is a mandatory step before an instrument-based identification/determination step. Classically, multiple separatory funnel partitions between immiscible solvents are used. The most commonly used solvent pair is n-hexane–acetonitrile,\(^{18,9}\) whilst n-hexane–dimethylformamide (DMF)\(^{112}\) and n-hexane–dimethyl sulfoxide (DMSO)\(^{113}\) are also useful. Most of the lipidic material remains in the nonpolar solvent (e.g. n-hexane) while pesticide residues are partitioned into the polar solvent (e.g. acetonitrile) of the above-mentioned pairs. Unfortunately some of the most nonpolar pesticides such as HCB, mirex, and highly chlorinated PCBs also partition into the nonpolar phase. The so-called p-value, defined as the fraction of the analyte partitioning into the nonpolar phase of an equi-volume two-phase system, gives a measure of the ability of the polar solvent to extract the analyte of interest.\(^{114}\) The higher the p-value, the lesser the partitioning into the polar solvent. OC and PYR pesticides show a wide range of p-values in the n-hexane–acetonitrile partition system, ranging from 0.91 (mirex) (lipophilic compound) to 0.035 (endosulfan sulfate) (more polar compound).\(^{114}\) The p-values of some of the OC and PYR pesticides are reported in Table 3. The recovery into acetonitrile is almost complete after four partition stages using a 1:2 nonpolar–polar solvent ratio as it is normally applied.\(^{18,9}\) However, the recovery of HCB and mirex (the most lipophilic OC pesticides) is barely satisfactory (ca. 70%). Being more polar than OC, PYR pesticides strongly partition into acetonitrile. Up to 3 g of fat dissolved in 15 mL...
of n-hexane can be extracted with four 30-mL fractions of acetonitrile. However, the removal of lipidic material is largely dependent on the type of fat. The removal is better with saturated fats, while it is less satisfactory with unsaturated oils such as fish oils. Furthermore, secondary components of fats, such as sterols and tocopherols, are extracted into the polar solvent and should be removed by further cleanup steps before GC with electron capture detection. MS detectors may avoid this problem.

In this approach, once pesticides have been extracted into acetonitrile, this solvent is generally exchanged because it is not amenable to most of the subsequent analytical steps, and interferes with electron capture detection. Three main methods have been used.

First, acetonitrile can be concentrated to dryness by typical rotary evaporation techniques under reduced pressure. The azeotropic distillation of acetonitrile after the addition of methanol (acetonitrile–methanol, 4:1 v/v) or addition of n-hexane (acetonitrile–n-hexane, 1:3.5 v/v) helps to lower the boiling point and to reduce losses of volatile analytes (e.g. HCB). The small amount of lipidic material present in the acetonitrile acts as a “keeper”, i.e. reduces or avoids the loss of lipophilic analytes by solubilizing them during the concentration process. In this way, all the components present in the acetonitrile remain in the extract and a different solvent is used for the next cleanup step.

In a classical method, acetonitrile is diluted with saline solution until its concentration in the solution is about 15% and pesticide residues are extracted from the aqueous acetonitrile solution into a low-boiling solvent by multiple partitioning steps. This type of partitioning is termed “back” extraction. For low polarity lipophilic compounds, such as OC and PYR pesticides, low polarity petroleum ether is appropriate, because it removes less coextractives from the aqueous phase. For more general multiclass methods, DCM is more suitable. The petroleum ether solution can be easily concentrated and subjected to further cleanup steps after solvent exchange, if necessary. In this way, some more polar components present in the acetonitrile extract could be removed by the aqueous phase.

In a third method, acetonitrile is diluted with water until its concentration is about 30% in water and the solution is passed through a reverse-phase cartridge (usually C18) that retains lipophilic pesticides (and other compounds). After drying the cartridge, OC and PYR pesticides can be recovered by eluting with a low-polarity solvent mixture such as toluene–n-hexane (3:97 v/v), which is suitable to be transferred on-line to an adsorption chromatography cartridge.

As in the case of nonfatty samples, a separatory funnel can be avoided in the n-hexane–acetonitrile partitioning step by absorbing the n-hexane solution into a macro-porous diatomaceous material. This acts as a support for the partition process, which is carried out by eluting the bed with acetonitrile saturated with n-hexane. Compared with the separatory funnel, the solid matrix partition process is simple and rapid and uses small volumes of solvent (typically 1 g of fat requires 15 mL of acetonitrile and 4 mL of methanol for azeotropic distillation). It is also able to satisfactorily recover from relatively nonpolar compounds such as OC and PYR to polar OP pesticides, while HCB shows a slightly lower recovery (ca. 60%) than the separatory funnel operation. In these applications, a C18 cartridge is used downstream to the partition cartridge for in-line further removal of fatty matrix. The recovery of 15 OC pesticides from 1 g of soya oil spiked at different levels is reported in Table 4.

In other methods the partition process is carried out by dispersing the extracted fat or fat solution over a chromatographic material that is used to retain the fat and from which OC pesticides are recovered by eluting with acetonitrile or water–acetonitrile mixtures. Alumina eluted with water–acetonitrile (20:80 v/v), Florisil eluted with water–acetonitrile (10:90 v/v) (both followed by back extraction of pesticide residues into petroleum ether), Celite eluted with DMSO, C18 eluted with acetonitrile or silica gel over PS–DVB have been found to be useful for this purpose.

4.2 Size-exclusion Chromatography

SEC (often referred to as gel permeation chromatography) is one of the most commonly used cleanup steps to separate pesticide residues from high molecular weight coextractives and fats. The most popular column material in SEC is a cross-linked styrene divinylbenzene (DVB) resin which is eluted with solvent mixtures such as toluene–ethyl acetate or cyclohexane–ethyl acetate.
for vegetable extracts, and cyclohexane–DCM or n-hexane–DCM for fats.

The predominant mechanism of separation relates to the difference in the molecular size between many of the coextractives and the pesticide residues, which generally have molecular weights lower than 500 amu. The resin also exhibits an adsorption mechanism which is mostly masked by the polar solvent used in the mixture. The larger compounds such as fats, oils, and the major part of vegetable coextractives elute earlier ("dump" fraction) than the pesticide residues ("collect" fraction). One of the major features of SEC is that it is a nondiscriminative cleanup very useful in multiclass multiresidue methods. Large columns (ca. 45 cm × 2.5 cm ID) have been used that are eluted at 5 mL min⁻¹ and require about 350–400 mL per sample ("dump" fraction + "collect" fraction + column wash). The collect fraction is about 100–150 mL. Large columns (300 mm × 19 mm ID) eluted with DCM at 5 mL min⁻¹ and with "collect" fraction of 20 mL are used in the cleanup of OC and PYR pesticides by high-performance size-exclusion chromatography (HPSEC). The recovery of 15 OC pesticides from 500 mg of spiked soya oil through HPSEC cleanup is reported in Table 5. Also, smaller columns (10 mm ID) for low-pressure chromatography or 7.8 mm ID for HPSEC have been used both for OC and PYR pesticide cleanup and allow a substantial 10-fold saving of time and solvent. The column is also reusable, and SEC lends itself to automation. Apart from requiring expensive instruments, SEC is a sequential cleanup procedure, limiting the number of samples that can be processed in a given period of time.

### Table 4
Recovery values of 15 OC pesticides extracted from ca. 1 g soya oil spiked at different levels and analyzed after Extrelut-3/C₁₈ cleanup followed by Florisil adsorption chromatography, according to the method in Di Muccio et al.¹⁰⁶

---

After SEC cleanup (and a concentration step), the nonfatty sample extracts are normally suitable for GC analysis using a selective detector such as an electron capture detector (ECD), a thermionic nitrogen–phosphorus detector (NPD), and/or a flame photometric detector (FPD) without further cleanup. However, for the
determination of OC pesticides by GC/ECD at the lowest levels a further cleanup by adsorption chromatography is often necessary.\(^\text{121}\)

SEC offers the opportunity of diverting the “collect” fraction directly to a cartridge of chromatographic material for further cleanup on-line. For instance, when low polarity solvent mixtures are used in the SEC of fats, the collect fraction can be purified by adsorption chromatography by passing it through a silica gel cartridge.\(^\text{125}\) This avoids the usual sequence of operations, such as collection of the fraction, concentration, solvent exchange, and quantitative transfer to the adsorption column. In a similar application for vegetables, the collect fraction can be passed through a cartridge of active charcoal for on-line removal of pigments.\(^\text{126}\) The removal of high molecular weight components by SEC, that are not necessarily removed by adsorption chromatography cleanup, is beneficial to the subsequent GC determination in that it avoids contamination of the injection port and column. Furthermore, micro SEC can be coupled on-line to a gas chromatograph by means of valve switching technology and using a gas chromatograph equipped with a large volume injection system.\(^\text{125}\)

**4.3 Sweep Codistillation – Assisted Distillation**

Sweep codistillation is a technique of cleanup based on thermal degradation of the coextractives including lipidic material and distillation/entrainment of the pesticide residues. In classical operation, the solvent solution of the raw extract (maximum 1 g of fat) is injected into a hot tube filled with glass beads in a stream of nitrogen. Most of the coextractives and the lipidic material adhere to the filling material. Further injections of solvent into the tube elute the pesticide residues via distillation with the hot stream of the nitrogen (sweep codistillation). In more recent developments, the fat is not degraded, but rather deposited in a special void tube held at high temperature. The fat spreads as a thin film over the inner walls of the tube, which is swept by nitrogen, and no injections of solvent are necessary (assisted distillation).\(^\text{128–130}\)

To recover the pesticide residues, the effluent is passed through a cold trap and then transferred off-line for a further cleanup. In commercially available systems designed for OC pesticides, the effluent is passed on-line through a cartridge of Florisil for further adsorption cleanup prior to the GC/ECD analysis.

The technique is mainly suited to OC and other fairly stable compounds due to the high temperature involved. Temperatures are in the range of 200–250 °C and typical nitrogen flow is in the range of 200–250 mL min\(^{-1}\). Apparatus is commercially available for processing several samples in parallel.

**4.4 Column Chromatography**

Adsorption chromatographic cleanup separates the coextractives on the basis of their polarity. Thus, it is appropriate for separation of low polarity compounds such as OC pesticides from the more polar coextractives present in the extracts. Adsorption chromatography under gravity alone was the cleanup of choice in the early days of pesticide residue analysis and it is still widely used. When instruments were not so sensitive as today and large analytical samples were extracted, a large amount of coextractives had to be removed. Consequently columns consisted of 10–20 g of adsorption material which required two to three fractions of 100–200 mL solvent each.

Now, instrumental sensitivity satisfactorily allows the use of adsorption cleanup on smaller columns (1–5 g of adsorbent eluted with fractions of 10–50 mL) as the sole cleanup when a small sample aliquot is extracted, or as a supplemental cleanup after the large-capacity cleanup steps already described.

Column chromatography as cleanup can also be used to collect a single fraction containing a wide range of pesticides with appropriate solvent(s). This approach is mostly useful in multiresidue methods to analyze for as many pesticides as possible. Of course, this approach requires sufficient resolving power in the identification step. However, the fractionation of the extract simplifies analyte identification and reduces the number of potential interferences in the collected fractions. Furthermore, the appearance of tentatively identified analytes in the expected fraction adds further evidence to the analyte confirmation. However, fractionation of the extract increases the number of identification processes. With adsorbents such as Florisil, alumina, and silica gel the reliability of the fractionation mostly relies on controlling and maintaining the right degree of activation/deactivation.\(^\text{9,45,131}\) For this reason, adsorption columns and cartridges are used for just a single sample and are not reused.

In the case of OC and PYR pesticides, the most frequently used adsorbents are Florisil, alumina, and silica gel. Depending on the particular application, these sorbents can be used either “activated”, i.e. heated at a temperature high enough to release most of the moisture, or “deactivated” with addition of 1–10% (w/w) water. The more active the material, the more coextractives and fat that are retained. Partial deactivation allows the use of a less polar eluent, while maintaining sufficient retention of the fat. OC pesticides are eluted with hydrocarbon solvents or low polarity mixtures, but more polar eluting mixtures are required to recover oxygenated OC pesticides, such as dieldrin, endrin, heptachloroepoxide, and oxychlordane, while PYR pesticides require significantly more polar
eluents. However, more polar eluents generally lead to “dirtier” fractions. Apolar fractions are almost free of lipidic material, while a few milligrams may appear in the polar ones. Water deactivation allows the use of less polar eluents. Hence 10 g of 5% water-deactivated Florisil, eluted with 200 mL of diethyl ether–petroleum ether (6:94 v/v), has been used to clean up PYR extracted from wheat and vegetables.\(^{37}\)

With Florisil macrocolumns (ca. 20 g) two eluting schemes are well known and are continuously updated with a number of new pesticides. In the first scheme, three fractions are collected eluting with 6%, 15%, and 50% ethyl ether in petroleum ether, while in the second scheme three fractions, consisting of 20% DCM in \(n\)-hexane, 50% DCM + 0.35% acetonitrile in hexane, and 50% DCM + 1.5% acetonitrile in \(n\)-hexane, are used.\(^{8,9}\)

Examples of Florisil minicolumns include: (1) a 2.5-g column eluted with \(n\)-hexane–benzene–ethyl acetate (180:19:1 by vol.) for OC pesticides,\(^{32}\) and with \(n\)-hexane–benzene–ethyl acetate (176:19:5 by vol.) for PYR pesticides;\(^{166}\) (2) a 4-g column eluted with one fraction of 50% DCM + 1.5% acetonitrile in \(n\)-hexane for OC and PYR;\(^{9}\) (3) a 5-g column of 10% water-deactivated Florisil eluted with diethyl ether–\(n\)-hexane (4:96 v/v) for OC.\(^{132}\) The fractionation of 28 OC pesticides and 20 PCBs from a 2.5-g Florisil column eluted with a three-eluent scheme is reported in Table 6. Application of Florisil cleanup to PYR pesticides also include: (1) a 10-g column eluted with 100 mL of ethyl acetate–\(n\)-hexane (3:7 v/v);\(^{133}\) (2) a 6-g column eluted with 6 mL of \(n\)-hexane–diethyl ether (7:3 v/v);\(^{134}\) (3) a 0.5-g minicolumn eluted with 5 mL of toluene;\(^{30}\) (4) a minicolumn of 0.5 g of Florisil + 0.04 g of active charcoal eluted with 5 mL of toluene.\(^{31}\) A minicolumn of 4 g of Florisil + 1 g of active charcoal eluted with 40 mL of toluene–acetonitrile (98:2 v/v) has been used for the cleanup of extracts from vegetables.\(^{32}\) A similar, smaller column (1.6 g Celite + 0.4 g charcoal eluted with 50 mL of acetonitrile–toulene (3:1 v/v)) is the cleanup used in a multiclass, multiresidue method for fruits and vegetables.\(^{20}\)

Alumina in large columns (15 g of acidic alumina eluted with 160 mL of DCM) has been used as a very common cleanup step before the GC/ECD determination of OC and PYR pesticides in grains.\(^{38}\) A minicolumn of 1 g of 10% water-deactivated alumina has been used for the separation of OC pesticides from 70–100 mg of fat.\(^{135}\) However, the control of the deactivation process is done by recovery trials of critical compounds and, due to poor batch-to-batch reproducibility, the deactivation has to be repeated with new batches.\(^{76}\)

Popular multiresidue schemes with silica gel include: (1) a 5-g column eluted with five fractions of \(n\)-hexane, \(n\)-hexane–benzene (4:6 v/v), benzene, benzene–ethyl acetate (1:1 v/v), and ethyl acetate to elute a diversity of

of acetone. (23) (2) a 1-g column of 1.5% water-deactivated silica eluted with five fractions of increasing polarity (n-hexane–toluene (65:35 v/v), toluene, toluene–acetone (95:5 v/v), toluene–acetone (80:20 v/v), and acetone) for over 400 compounds including OC and PYR; (10,26) and (3) a 1-g column eluted with four fractions of n-hexane, benzene–n-hexane (60:40 v/v), benzene, and ethyl acetate–benzene (50:50 v/v), to separate 50 OC pesticides and PCB. (136) An application for PYR pesticide residues from fruits and vegetables is based on a 5-g silica column eluted with 25 mL of n-hexane–DCM (4:1 v/v) and 60 mL of DCM (contains the analytes). (137) An application of silica gel to OC, OP, and triazines in wine is based on a 15-g column eluted with 40 mL of n-hexane, 16 mL n-hexane–benzene (1:1 v/v) and 50 mL of acetonitrile. (74) Sequential application of Florisil cleanup and silica fractionation has been used for PCBs in human serum. (44)

4.5 Solid Phase Extraction Chromatography

Currently, ready-to-use cartridges filled with 0.1–1 g of classical adsorbents (alumina, silica, Florisil, carbon), the so-called SPE cartridges, are increasingly used to miniaturize the cleanup; this saves solvents and time, and allows automation of the cleanup step.

C$_{18}$ cartridges are used to reduce or retain lipophilic coextractives when acetonitrile or aqueous acetonitrile extracts from either fatty (46,49,51,116,117) or nonfatty samples (21,110) are passed through. It has been noted that most pesticides elute off a C$_{18}$ cartridge with an eluent of water–acetone (75:25 v/v) (which is about the composition of the aqueous acetonitrile from the extraction of vegetable samples), while lipids and other highly lipophilic coextractives are retained. (21) In a different way, aqueous acetone, (29) or aqueous acetonitrile (110) resulting from the extraction of vegetables, can be further diluted with water and passed through a lipophilic C$_{18}$ (110) or PS–DVB (29) cartridge to retain the analytes. After retention, C$_{18}$ and PS–DVB cartridges are dried with a nitrogen stream and the analytes are recovered with solvents such as ethyl acetate or toluene–petroleum ether (3:97 v/v). (49,51) The latter, being of low polarity, can be passed directly to a Florisil cartridge for subsequent adsorption cleanup, (49,51) avoiding the usual sequence of linking steps (collection, concentration, solvent exchange, quantitative transfer).

Florisil is used to remove polar coextractives in the analysis of both fatty (49,51) and nonfatty (29) sample extracts. In an application of Florisil SPE cartridges to OC in fish, crab, and milk, the eluting mixture was diethyl ether–petroleum ether (2:98 v/v), (49,51) while it was acetonitrile–n-hexane (15:85 v/v) for PYR pesticide residues in paddy rice. (138) Alumina SPE has also been used for adsorption cleanup of fatty extracts. (118)

SPE-NH$_2$ has also been used in normal phase cleanup in multiresidue methods for nonfatty (15,21) and milk samples. (48) It is usually eluted with DCM–methanol (97:3 v/v) (46) or DCM–methanol (99:1 v/v). (15)

In a multiresidue method based on acetonitrile extraction, after separating the water with the “salting out” procedure, a portion of the acetonitrile extract is cleaned up with a minicolumn of 2 g of charcoal–Celite (1:4 w/w) or on a carbon SPE cartridge of 500 mg. The pigments are mostly retained while the pesticides are eluted with acetonitrile–toluene (3:1 v/v). (20) It is noteworthy that HCB is poorly or not recovered through carbon, depending on the type of material. Such a cartridge has been used also downstream from an SEC column eluted with cyclohexane–DCM (1:1 v/v) to trap pesticides for subsequent SPE cleanup. (126) Another way of removing pigments from fruits and vegetable extracts is the use of an SAX (strong anion exchanger) or an SAX/PSA (propylethylenediamine–silica): the extract is applied in DCM and eluted with DCM. (54)

The great advantage of cleanup on an SPE cartridge is that it is amenable to robotic manipulation for unattended processing of large sequences of extracts. Also SPE cartridges are ready-made, disposable, and reduce solvent consumption, time, and labor.

4.6 High-performance Liquid Chromatography

Semipreparative HPLC on a column of 250 mm $\times$ 9.2 mm ID filled with porous spherical silica particles and eluted with 20% DCM in n-hexane has been used to separate five OC pesticides and PCB from 300 mg of butter fat. (139) By using column switching technology, fully automated sample cleanup and fractionation of 10 OC pesticides and PCB from 45 mg of fat was achieved by normal phase chromatography using a short column and an analytical column of silica gel. (45) A rapid automated offline cleanup on a silica gel HPLC column has been reported for the cleanup of 45 mg of fat in 32 min per sample. (140) Advantages include high separation power and reproducibility, and reusability of the column.

An automated sample cleanup and fractionation has been used for the analysis of mussel extract using normal phase high-performance liquid chromatography (NPHPLC) with a column of silica (150 mm $\times$ 3.9 mm ID) eluted stepwise with 4 mL each of n-hexane, n-hexane–ethyl acetate (99:1 v/v), and ethyl acetate for the separation and collection of compounds of different polarity. (141) NPHPLC on aminopropyl silica has been used after lipid separation by SEC for the cleanup and group separation of PCB and OC pesticides in cod liver oil. The column was eluted with two fractions: the first (10 mL of n-hexane) elutes the nonpolar PCB,
HCB, DDE, and mirex, and the second (32 mL of n-
hexane–DCM (90:10 v/v)) elutes the more polar HCH,
DDD, DDT, and chlordane.\(^{142}\)

### 4.7 Thin-layer Chromatography

Due to its high separation capabilities, TLC can also
be used as a mini preparative, highly selective cleanup.
Crude or partially cleaned up extracts equivalent to
2–10 g of product (acetone extraction and partition
into DCM) can be applied bandwise on a standard
20 mm × 20 mm × 0.25 mm silica gel plate. After the
development, compounds of interest can be recovered
from the plate by scraping the band at the appropriate
retention factor \(R_f\) (identified by running the target
compound(s) alongside at higher concentration) and
eluting the silica material with a suitable solvent.
Compound(s) recovered are highly cleaned up and
are suitable for identification/determinative techniques.
The agreement between the \(R_f\) and the response from
the identification techniques adds further evidence for
confirmation of the tentatively identified compounds at
residue level. As a cleanup step, TLC has high separation
power but low capacity and, therefore, complements a
high-capacity, low resolving power cleanup, such as SEC
or partition processes.\(^{8,143}\) TLC is inconvenient but can
increase throughput due to parallel operation.

### 4.8 Degradative Cleanup

Degradative cleanup for samples of plant and animal
origin can be accomplished by chemical treatment which
converts many coextractives into chemical species that
are no longer extractable, or permits their easy removal
with a selective process.

Due to their relatively high chemical stability, strong
degradative cleanup has often been applied to extracts for
the analysis of OC pesticides. Relatively mild degradative
cleanup is conceivable for PYR and other classes of
pesticides.

Concentrated sulfuric acid treatment is a classical
method to destroy organic matter in raw extracts. It
has been applied either by shaking a solution of the
extract with sulfuric acid,\(^{144,145}\) or by passing the solution
through a column of inert diatomaceous material.\(^{146}\) The
recoveries of 22 OC compounds through a sulfuric acid
impregnated Extrelut cartridge are reported in Table 7. A
small amount of silica gel impregnated with concentrated
sulfuric acid has been used as the bottom layer in a bilayer
MSPD column for the extraction of PCBs in fish.\(^{147}\)

Alkaline treatments have been used to saponify and
remove the fatty material. They can be given either by
passing the solvent solution through a column of MgO
mixed with diatomaceous material,\(^{89}\) or by treatment with
10% KOH in ethanol.\(^{43,145}\) In the first case the solvent

\(a\) Recovered as endrin ketone, which appears as a peak with a retention
time longer than that of the parent compound.
\(b\) Not investigated.

Unpublished data from the laboratory of the author.

Both sulfuric acid and alkaline treatments have been
used either as the sole cleanup for the analysis,\(^{42,43}\) or as
a supplemental cleanup after some of the main cleanup
steps described above.

Degradative cleanup, however, can introduce some
transformation of the analyte(s) of interest. Most OC
pesticides including PCNB and PCB are stable under
acidic conditions except dieldrin, which is destroyed;
derdin, which is converted into endrin ketone; and
methoxychlor, which is partially destroyed.\(^{146}\)

HCB, cyclodiene pesticides (heptachlor, heptachlor-
epoxide, aldrin, dieldrin, endrin, and mirex) and DDE
are stable under alkaline conditions at ambient tem-
perture, while PCNB is slowly degraded, and DDT,
DDD, and methoxychlor are dehydrochlorinated to the
corresponding olefins.\(^{145}\) Dicofol is fairly stable at ambi-
ent temperature,\(^{145}\) but it is converted to DCBP in
strong alkaline conditions.\(^5\) HCHs are converted into trichlorobenzenes.\(^{148}\) As esters, PYR pesticides are degraded under alkaline conditions.

Silica gel, alumina, or Florisil impregnated with sulfur nitrate have been used for the removal of some sulfur-containing compounds from extracts of onions and kale.\(^{149}\) By the addition of NaBH\(_4\) prior to sample extraction with acetonitrile, nearly all matrix interferences (organosulfur compounds) can be eliminated from green onion samples.\(^{21}\)

Oxidative cleanup with KMnO\(_4\) solution has been used in the analysis of vegetables.\(^{150}\)

The alteration of some analyte(s) may be used to remove or separate them from other analytes, for instance, the oxidation of DDE to DCBP and its separation by adsorption chromatography can eliminate this interference in the analysis of PCB.\(^6\) Also this approach can be used to convert the analytes into species with better chromatographic, sensitivity, and selectivity properties. Derivatization of the analytes into species whose detection is a confirmation of identity is also sometimes necessary. For instance, detection of endrin ketone after acid treatment is diagnostic for endrin, and detection of a specific late-eluting peak after reaction with a hydrobromic acid–acetic anhydride mixture is diagnostic for dieldrin, whose epoxide ring is opened under these conditions.\(^{151}\) HCB can be converted into later-eluting monoisopropoxypentachlorobenzene and disopropoxytetrachlorobenzene for confirmation of identity.\(^{152}\) The formation of compounds with longer retention times in GC is beneficial because usually most of the matrix interference appears in the early portion of the chromatogram.

As stated above for dicofol,\(^{63}\) degradation of analytes during the analytical process is also possible.

In the analysis of PCB and OC pesticides in environmental samples, especially soil and sediments, it is necessary to remove elemental sulfur to obtain a good GC/ECD chromatogram. The removal is carried out by activated copper powder,\(^{51}\) with tetrabutylammonium sulfate, or with SEC.\(^7\)

5 IDENTIFICATION AND DETERMINATION

5.1 Gas Chromatography

OC and PYR, as well as other classes of pesticides which have relatively low molecular weight with sufficient volatility, are most commonly analyzed by GC. A great number of developments and improvements in GC and related detectors has been made in connection with the analysis of pesticide residues in food and environment. The relative simplicity and ease of operation, together with the high separation power and an array of sensitive and selective detectors, make GC the technique of choice for determination of thermally stable pesticides.

5.1.1 Packed Columns

The first GC applications involving pesticide analysis were developed on packed columns. Early columns were generally glass tubes 1–2 m long, 2–4 mm ID, filled with a solid, high surface material covered with 1–5% (w/w) of thermally stable, low volatility polymers. A variety of stationary phases including methyl silicone (DC-200, OV-1, OV-101, SE-30), methyl phenyl silicone (OV-17, DC-710), fluoropropyl silicone (QF-1, OV-210), cyanopropyl silicone (XE-60, OV-225), polyethers (Carbowax 20 M), and polyesters (DEGS, NPGS) allowed a diversification of selectivity, which can be further expanded by packing the columns with mixed packings, such as 5% DC-200 + 7.5% QF-1, 1.5% OV-17 + 1.95% QF-1, 1.5% SP-2250 + 1.95% SP-2401, 5% OV-101 + 3% OV-225, and 5% OV-61 + 3% XE-60 + 5% QF-1.\(^{8,9,11,151–153}\) The chemical composition of the main stationary phases and trade codes are reported in Table 8.

Although packed columns have almost been entirely superseded by capillary columns, they could have useful application in the screening of a few target analytes in dirty extracts. Indeed, the injection of coextractives into the first, hot portion of the packing material provides an extra cleanup by irreversible adsorption or thermal degradation. However, thermally labile compounds suffer from the activity of the packing material.

5.1.2 Capillary Columns

Nowadays, pesticide residue analysis is almost always carried out on fused silica capillary columns. In this approach, columns from 10 to 60 m with IDs of 0.18–0.53 mm (0.18 mm, “microbore”); 0.25 mm, “narrow-bore”; 0.32 mm, “wide-bore”; 0.53 mm, “megabore”) are commercially available. Smaller diameter columns have greater separation capabilities, but also have a smaller sample capacity and limited lifespan. The liquid stationary phase is normally chemically bonded to the inner surface of the columns, and film thicknesses used in pesticide residue analysis are typically in the range 0.25–1.5μm. The special preparation of the inner surface and the coverage of the film give a high degree of inertness that allows the analysis of relatively labile and/or polar compounds. A variety of polymers of similar nature to the packed columns are available for capillary columns, and even specially prepared columns are available to suit specific separations, such as the “608” series columns for OC pesticides listed in EPA Method 608.\(^{154}\)

</table>

The type and dimension of the column depend on the type of analysis and analyte/matrix combination. In routine pesticide analysis of fruits and vegetables, megabore columns of 15 m × 0.53 mm ID × 0.8–1.5 μm film thickness provide sufficient separation in a short time combined with a good capacity and ease of operation. In large, multiclass, multiresidue methods for monitoring pesticide residue in foods, columns of 30 m × 0.25 mm ID × 0.25 μm film thickness are most commonly used. For highly demanding environmental analysis regarding the analysis of complex mixtures of environmental contaminants such as PCBs and camphor (toxaphene), columns of 60 m × 0.18–0.25 mm ID × 0.18–0.25 μm film thickness are used. The most widely used stationary phases are the 100% dimethyl polysiloxane (“code-1”), the 5% diphenyl–95% dimethyl polysiloxane (“code-5”), the 35% diphenyl–65% dimethyl polysiloxane (“code-35” and “code-608”), the 50% diphenyl–50% dimethyl polysiloxane (“code-50” and “code-17”), and the 14% cyanopropylphenyl–86% dimethyl polysiloxane (“code-1701”) phases. Each phase has a particular selectivity and is better suited to particular separations. The most commonly sought OC pesticides are better separated on a “608” phase, including the critical pair DDE–dieldrin. The group of early eluting HCB and HCH isomers is better separated on a “1701” phase. Some pairs of OC pesticides, including DDE–dieldrin, cis-heptachloroepoxide–oxychlordane, cis-chlordane–trans-nonachlor, o,p′-DDT–endrin, and β-endosulfan–p,p′- DDD, are considered critical. A number of critical pairs are found in complex PCB mixtures, for instance, PCB 55/60, PCB 138/178. Analyses on columns of different polarity are usually carried out to resolve critical pairs.

Continuing research is dedicated to the development of new phases to meet the stringent requirements of the separations needed for complex mixtures of OC compounds such as PCB and toxaphene in environmental samples. Toxaphene consists of several compounds with a different degree of chlorination and most of them are chiral. Enantiomers often have different toxic and degradative properties. Enantiomer separation has been carried out on chiral capillary columns. Tandem columns, i.e. systems made of a combination of a column that gives isomer-selective separation and a column that gives enantiomer-selective separation, can be optimized for the isomer- and enantiomer-selective separation of toxaphene. PYR are currently analyzed by using conventional GC phases where only the separation of the stereoisomers occurs.
(with three asymmetric carbon centers giving eight enantiomers) shows only four peaks corresponding to the four pairs of enantiomers, eluting in the order cis, trans, cis, trans from a low-polarity column.\(^{153}\)

Being chemically bonded to the surface, the stationary phase is more stable and, after being subjected to high-temperature conditioning, releases a low “bleeding” even at high temperature, so that detectors can be operated at higher sensitivity and programmed temperature operations are possible and still maintain a flat baseline. Temperature programming and the high resolving power of the capillary columns allow the analysis of a wide variety of analytes in complex mixtures in a single run.

5.1.3 Injectors

While injection into packed columns is quite simple, special injectors and injection techniques have been developed to fully exploit the separation power of capillary columns. Injection can be carried out either in a “liner” (an injector chamber held in the injector oven to which the column is connected) or “on-column”. Injection into a liner is carried out with conventional microsyringes through a polymeric rubber septum. On-column injection into narrow- and wide-bore columns is carried out through special valves and requires tiny needles and special alignment systems. However, “liner”-type on-column injection is possible with conventional techniques into the first portion of a megabore column held in the injector oven. Autoinjectors also work more simply and reproducibly when injection is made into liners or on megabore columns.

The site of injection, either the liner or the beginning of the column in on-column operation, is located in the injector oven. At the time of injection the temperature can be kept either high enough to vaporize all the components (hot or flash vaporization) or suitably low to allow the vaporization of the solvent only, with the analytes being vaporized on temperature programming (temperature programmable injectors). The injection chamber (the liner) and the column can be connected so that all the sample injected is transferred to the column, or part of the vapor produced upon injection can be “split” and vented outside (split injectors). In pesticide residue analysis, as in general in trace analysis, one is interested in maximum sensitivity. Thus, split injectors are operated in “splitless” mode. In this mode, the split vent of the injection chamber is closed for about a minute to allow the almost quantitative transfer of the sample into the column, and then the split vent is opened to sweep the residual vapor from the injection chamber.

Regardless of the type of injection, the vapor produced by the usual injection volume (1–3 µL) would flood the column and spread the analytes along a great length of the column unless special operating techniques were used. To refocus the analytes into a narrow band at the beginning of the column, the temperature of the column oven is kept relatively low (cold trapping) while the analytes are transferred from the injection site into the column. Furthermore, with proper selection of the column temperature with respect to the boiling point of the solvent injected, solvent vapors are temporarily condensed, which leads to a temporary increase of the film thickness of the stationary phase. This leads to the enhancement of the retention properties of the column in that zone and refocusing effects on the analytes (solvent effect).

Injection is usually done through a septum made of special silicone polymers. At high temperature, a certain bleeding occurs and possibly leads to ghost peaks in the chromatogram. Thus, septum injectors in trace analysis are normally equipped with a septum purge line, i.e. a small stream of the carrier gas that sweeps the inner face of the septum to vent much of the bleeding.

Usually volumes of 1–3 µL are introduced, but this depends on the type of injector. Hot vaporizing injectors should have liners with sufficient volume to accommodate the vapor, or else contamination of the carrier gas line can occur due to backflushing. Larger volumes give longer vapor residence time in the liner and contact with hot surfaces can enhance degradative effects on the analytes. To decrease the residence time, hot vaporizing injectors are better operated with megabore columns with flow in the range 5–10 mL min\(^{-1}\). To increase the volume available for the expansion of the vapor and to prevent or reduce the injected coextractives from entering the analytical column, a “retention gap” is usually inserted between the injector and the column. A retention gap (or guard column) is a length of deactivated fused silica column without stationary phase, and thus without appreciable retention. Retention gaps of 1–5 m are used. About 30–40 cm of the retention gap are removed after a certain number of injections, depending on the type of matrix, extraction, and cleanup. Multiclass, multiresidue methods that use a minimal cleanup require more frequent cuttings.\(^{15,21,25}\)

Injection liners are made of glass that is often deactivated by silanization. The inertness of the injection chamber can be monitored through the behavior of indicator compounds. For instance, appearance of DDE and DDD upon injection of DDT, and/or endrin aldehyde and endrin ketone upon injection of endrin, together with the shape of the peaks, is an indication of degradative activity. However, activity may be useful in certain cases. For instance, conversion of tralomethrin into deltamethrin in the injection chamber is part of the analytical method for the determination of
tralomethrin. As with packed columns, injection into hot vaporizing injectors introduces some degradation of the coextractives, which can lead to beneficial effects on the life of the column and quality of the chromatograms. Injection into cold injectors is preferable for heat-labile compounds, but often gives rise to more complex chromatograms.

When high sensitivity is desirable, large volumes of solvent can be injected with special techniques. In one approach, the injector can be kept at subambient temperature while repeatedly injecting the solution, or, with the “cryo focusing” technique, a short length of the column can be cooled to focus the analytes. In a special apparatus, the large volume of vapor generated by the injection is vented outside by activating an “early exit” valve during the concurrent evaporation of the solvent in the injector and retention gap. Increasing the portion of the analytical sample injected allows a reduction in size of the aliquot of analysis and the analytical process, which is especially useful for instance when a large volume of water has to be extracted to attain low limits of determination.

Capillary columns are usually operated with helium as the carrier gas (less frequently hydrogen) since the optimum HETP (height equivalent theoretical plate) is maintained over a wide range of linear gas velocity. However, with conventional pressure- or flow-regulated systems, the change in flow rate due to column temperature programming is not taken into account, and the retention times and peak widths of low-volatility compounds increase. Most GC instruments now operate with electronic pressure control (EPC), which is a system able to maintain constant flow over the entire temperature program. This acts to reduce the analysis time and improve separation of compounds eluting at high temperatures, which is the case for some PYR pesticides. Pressure programming offered by EPC has been used to carry out pulsed splitless injection in conjunction with megabore columns. In this way, a high flow rate is used during injection to sweep the analytes out of the liner rapidly, thus reducing analyte loss due to adsorption or thermal degradation. This is useful for DDT/DDE, PYR, and polar OP pesticides. Also, pulsed splitless injection strongly reduces the chromatographic response enhancement caused by the so-called matrix effect.\(^\text{7,159}\)

5.1.4 Selective Detectors

The great advantage of GC separation compared to other techniques in trace analysis in general and in pesticide residue analysis in particular is the availability of an array of simple-to-operate, sensitive, and selective detectors, such as the ECD, electroconductivity detector (ECD), halogen-specific detector (XSD), FPD, NPD, and chemiluminescent detector (CLD).\(^\text{146,160}\)

The ECD is sensitive to compounds containing electron acceptor atoms or groups, such as halogen atoms, nitro groups, and unsaturated systems. OC pesticides by definition contain chlorine, while most PYR pesticides contain either chlorine, bromine, or fluorine. OC pesticides are usually analyzed by GC/ECD in a working range of 1–100 pg, while PYR pesticides are less sensitively measured in working ranges of 20–150 pg up to 50–500 pg, depending on the number and type of halogen in the molecules.\(^\text{116,117}\) Figure 1 shows typical GC/ECD chromatograms of a fish extract (analyzed with acetone–n-hexane extraction, solid-matrix partition for separation of fat and cleanup by Florisil adsorption chromatography). Standard mixtures of OC pesticides are shown for comparison in Figure 2. Typical GC/ECD chromatograms of two soya oil samples spiked with two different standard mixtures of PYR pesticides together...
with the corresponding standard mixtures are shown in Figures 3 and 4, respectively. For nonhalogen-containing pesticides, halogenated derivatives can be prepared to improve the detection with ECD. A recent development is the nonradioactive ECD. Conventional ECD uses a 63Ni foil as a source of electrons. In nonradioactive ECD, the nonradioactive ECD is used for the analysis of halogen-containing PYR and OC pesticides. Being halogen-selective, the ECD is less sensitive to nonhalogen, electron-capturing interferences than the ECD. A number of fatty foods were analyzed for OC pesticides. A recent development is the nonradioactive ECD. Conventional ECD uses a 63Ni foil as a source of electrons. In nonradioactive ECD, a pulsed discharge in pure helium generates high-energy photons that are used to photoionize a dopant gas added to the cell. The resulting electrons are used in the electron capture process. The pulsed discharge ECD offers several advantages over the ECD: (1) cleanliness, because the GC effluent does not come into contact with the ionization source; (2) linearity of four orders of magnitude; (3) sensitivity equal or better than the ECD; (4) low internal volume; and (5) elimination of the radioactive foil and associated safety measures. The ECD (or Hall detector) is based on the catalytic reduction of halogen-containing compounds that produce hydrohalic acids which are detected and measured through the increase of electrolytic conductivity in a cell flushed by propanol. It is more selective than the ECD for halogens and is used for the analysis of halogen-containing PYR and OC pesticides. Being halogen-selective, the ECD is less sensitive to nonhalogen, electron-capturing interferences than the ECD. A number of fatty foods were analyzed for OC and PYR pesticides after SFE extraction and cleanup, without further cleanup. The XSD has been specifically developed for the selective detection of halogen-containing compounds in GC. Unlike the EICD, the XSD does not require catalyst tubes, solvents, resin cartridges, a pump, or a transfer
N-selective detectors and interferences of N are greater some PYR contain N, they are not sensitively detected by in trace analysis for OC and PYR pesticides. Although N or S, respectively, but are not necessarily of interest detectors for compounds containing P or S, N and P, and 104 and a selectivity Cl/HC cathodic current is measured. XSD has a linear range of reaction of free chlorine atoms with this alkali-sensitized ions emitted from the anodic surface. The adsorption and cathodic surface is activated by neutralization of alkali their oxidation products and free halogen atoms. The efficiently converts compounds containing halogen to the effluent from a GC column. This oxidative pyrolysis reactor is operated in an oxidative mode, which pyrolyzes line. The XSD does not contain a radioactive source. The reactor is operated in an oxidative mode, which pyrolyzes the effluent from a GC column. This oxidative pyrolysis converts compounds containing halogen to their oxidation products and free halogen atoms. The cathodic surface is activated by neutralization of alkali ions emitted from the anodic surface. The adsorption and reaction of free chlorine atoms with this alkali-sensitized cathodic surface yields an increased thermionic emission comprised of free electrons and halogen ions. The total cathodic current is measured. XSD has a linear range of 10^4 and a selectivity Cl/HC > 10^4.

The FPD, NPD, and CLD are element-selective detectors for compounds containing P or S, N and P, and N or S, respectively, but are not necessarily of interest in trace analysis for OC and PYR pesticides. Although some PYR contain N, they are not sensitively detected by N-selective detectors and interferences of N are greater than S or Cl. Endosulfan can be detected via S with pulsed FPD (PFPD) or CLD. The new PFPD is based on a pulsed flame and combustible gas flow rate that cannot sustain a continuous flame operation, and a pulsed emission of light is obtained. The pulsed flame operation shows some interesting features in pesticide residue analysis, including increased sensitivity for P- and S-containing compounds along with the possibility of distinguishing between the two signals and selectivity for other elements such as N, Sn, that are of interest in pesticide residue analysis. The increased sensitivity for S would allow the detection of endosulfan and especially endosulfan sulfate. Indeed endosulfan sulfate, being more polar, usually occurs in dirtier fractions accompanied by more matrix interferences.

The coupling of a microwave-induced helium plasma atomic emission detector (AED) to GC has introduced multiple element selectivity for helping to identify organic chemicals in GC. Depending on the spectral lines selected, GC/AED can acquire signals for different elements in a single run. For example, Cl, Br, F, and N atoms for PYR and Cl for OC pesticides can be monitored. This technique is less popular than GC/MS because of expense, reduced sensitivity and a lesser degree of confirmation. AED has the potential in multiresidue analysis to detect compounds with metallic elements, for instance tin, and to complement other element-selective detectors or MS. Indeed assembling a matrix of retention time parameters and responses to selective detectors is a common approach to identify compounds in screening samples for multiple pesticides in fruits and vegetables.

5.1.5 Identification and Determination Procedures

For compounds analyzed by GC, tentative identification is based on matching the retention times or the relative retention times to those of standards. The minimum criterion for a tentative identification with selective detectors is the correspondence of the retention parameters on at least two columns of different polarity. Several compilations are available that give relative retention times on GC capillary columns of different polarity useful in multiclass, multiresidue analysis. To reduce time for identification, GC instruments are often equipped with twin injectors (or a single injector connected to two columns with a Y-splitter) for simultaneous injection into two columns of different polarity useful in two ECDs, or two different detectors, for instance an ECD and an ElCD in the determination of OC and PCB in foods and environmental samples. In multiclass, multiresidue methods an ECD or an ElCD is used in multiclass, multiresidue analysis.

The two chromatograms are acquired simultaneously. Cross matching the retention times helps the identification of the analytes.
Less frequently used is bidimensional GC in which a “heart cut” from the first column is transferred to a second column of different polarity.\(^{176}\) Comprehensive orthogonal GC on two short columns of different polarity connected through a two-stage thermal desorption modulator has been applied to analyze OC pesticides from human serum in a few minutes with powerful separation capabilities.\(^{156,174}\) In this case a complex bidimensional chromatogram is obtained that requires unconventional techniques for interpretation.

Further evidence for identification is provided by matching the analytical behavior through a combination of techniques based on different mechanisms of separation. Target compounds can be separated by adsorption TLC and transferred off-line to a gas chromatograph (matching \(R_f\) and retention time). Compounds separated by HPLC can be transferred to GC off-line or on-line. In on-line operation the peak of interest is trapped in a loop and by valve-switching transferred to a gas chromatograph equipped with a large-volume injection system. However these operations are useful for confirmation of target analyte(s) step by step.\(^{175}\)

In GC- and HPLC-based techniques quantitation is usually carried out through peak area comparison with solutions of the standard compound at known concentration and either using a multilevel calibration curve, or interpolating between two standard solutions whose responses “bracket” the response of the sample (bracketing standards).\(^{46}\) In some circumstances, single-point comparison is permissible.\(^{37}\) The use of an IS is preferred to control final volume and injected volume variations. Not infrequently a “matrix effect” is observed in quantitation of pesticide residues at low levels. The matrix effect describes the difference of the response of the analytes injected in pure solvent (the usual “solvent standards”) or mixed with the matrix components as they occur in the final extract (“matrix-matched standards”). Usually an increase in response is observed when the standard is injected with the matrix. Thus, if a sample component is quantitated against a standard in pure solvent, an overestimation of the component in the sample can often be observed. The matrix coextractives have a protective effect on the analyte during the injection and transfer into the column. The matrix effect depends on the nature of the compounds, and the performances of the GC injector. It is mostly apparent with polar, easily degradable compounds such as phosphoramides. Thus, the use of matrix-matched standards is recommended. The matrix effect has been observed withPYR,\(^{123}\) and to a lesser extent with OC pesticides.\(^{16,28,46,79,97,176}\) In a separate mechanism, in both GC- and HPLC-based quantitation the coelution of matrix components with the analyte, even if not detected by selective detectors, may alter the detector response. So, although certain analyses can be carried out with minimal cleanup, a more rigorous separation of matrix interferences may be beneficial from the quantitation and ruggedness points of view.

5.1.6 Gas Chromatography/Mass Spectrometry and Gas Chromatography/Fourier Transform Infrared Spectrometry

For on-line fast confirmation in multiresidue methods, GC takes advantage of the coupling to spectrometric identification techniques, such as MS and infrared (IR) spectrometry.

GC/MS is the most widely used technique for identification of organic GC-amenable compounds.\(^{177}\) GC/MS is of paramount importance in analyzing PCB and toxaphene in environmental samples, and for the identification of metabolites and degradation products, for instance, of chlordane,\(^{157}\) pentachloronitrobenzene,\(^{178,179}\) and cypermethrin.\(^{180}\) With modern benchtop GC/MS systems operating with capillary columns, the column is inserted directly into the ion source. Benchtop GC/MS instruments are based on either a quadrupole mass filter\(^{20,29,46,90,134,163,168,181,182}\) or an ion trap detector (ITD).\(^{99,97,99,115,183,184}\) The ITD also allows simple MS/MS operation, i.e. obtaining a mass spectrum from a previously formed fragment, that strongly increases the compound specificity of the technique.\(^{185,186}\) Different ionization techniques are available, such as electron impact (EI) and chemical ionization (CI) in positive or negative mode. EI ionization mode gives extensive fragmentation that is characteristic of the molecular structure of the compound. Most frequently used is GC/EIMS, for which large electronic libraries of spectra are available that can be searched by appropriate software available on the data station. This search can often be carried out in combination with other parameters such as retention time and elemental information to restrict the number of candidate identifications.\(^{166}\) Full spectra can be acquired with fractions of a nanogram, depending on the compound injected. Comparison of a full spectrum with the library spectrum and the spectrum of the authentic compound at the appropriate retention time gives almost unequivocal identification.

In selected ion monitoring (SIM) mode, also named multiple ion detection, MS is a sort of compound-selective detector tunable to different sets of ions. Decreasing the number of ions to be collected usually increases the sensitivity. Thus, SIM mode provides the highest sensitivity.

In multiresidue methods, for screening purposes the SIM mode is used, i.e. some diagnostic ions are followed in time windows appropriate to the detection of target compounds.\(^{120,46,90,123,134,181,187}\) For reliable identification, the appearance of one to three ions at the correct
retention time and with the correct intensity ratios is considered necessary.\textsuperscript{184} Several methods report a list of ions (m/z) that may be used to select diagnostic ions for SIM analysis.\textsuperscript{15,16,17,20,46} However, a full EI spectrum should be obtained for unequivocal confirmation. In this respect the ITD is very sensitive in full scan mode and full scan spectra can be obtained with sub-nanogram amounts.

CI (more commonly with methane) gives less fragmentation than the EI mode and spectra with only a few ions are recorded, with $M + 1$ or $M + CH_4$ being normally the most abundant in positive CI. The lesser fragmentation results in increased sensitivity. Although less definitive than the EI spectrum, the CI spectrum together with retention time data provides sufficient evidence for the presence of an analyte.\textsuperscript{69,184} Negative ion CIMS takes advantage of the electronegative character of polychlorinated compounds. Negative ion CIMS has been used to detect PCB and OC pesticides with high sensitivity in plant materials,\textsuperscript{29} human blood,\textsuperscript{182} and the environment.\textsuperscript{156} Negative ion CIMS with methane has also been used for the determination of four PYR in soil,\textsuperscript{134} and offers sensitivity of the same order of GC/ECD.\textsuperscript{153}

High-resolution MS is used as the ultimate identification technique at very low levels in food,\textsuperscript{46} and in environmental studies.\textsuperscript{71,156}

The gas chromatograph coupled to a Fourier transform infrared (FTIR) spectrometer is also a powerful identification technique but has not achieved widespread routine application in pesticide residue analysis.\textsuperscript{188}

### 5.2 High-performance Liquid Chromatography

With the development of high-performance columns and sensitive detectors the applications of HPLC to residues analysis are paralleling the GC applications. HPLC is primarily suited to the analysis of polar, low-volatility, and thermally labile compounds. This is particularly the case for the new classes of pesticides having more complex structures and increasing molecular weight. A limitation of HPLC compared to GC is the fewer types of detectors. Traditionally, the variable-wavelength ultraviolet/visible (UV/VIS) detector usually operated in the 200–350 nm range and the fluorescence detector are the main choices. Most OC pesticides are poorly detected by either technique and for them HPLC has been used mainly as a separative cleanup, as mentioned previously. PYR can be analyzed at residue level by the UV detector.\textsuperscript{32,38,138,139} Particularly for nonhalogen-containing PYR, such as allethrin, fenpropathrin, phenothrin, resmethrin, and tetramethrin, HPLC can provide the only determinative technique at residue level apart from GC/MS.\textsuperscript{153}

Reverse-phase chromatography either on octyl-silica (C$_8$) or octadecyl-silica (C$_{18}$) is the most popular separation mechanism, where low polarity compounds, such OC and PYR pesticides, are strongly retained, while more polar compounds elute earlier.

Fluorescence detection is useful for naturally fluorescent compounds or compounds that can be derivatized to fluorescent compounds. HPLC with fluorescence detection has been used for the determination of residues of piperonyl butoxide, a synergist used in PYR formulations, in rice, grains, and beans.\textsuperscript{153}

The analysis of single enantiomers is important not only to characterize the formulated products, but also for appropriate assignment of the MRL value in residue analysis.\textsuperscript{153} Chiral phases are available as HPLC columns that permit the separation of some of these enantiomers.\textsuperscript{153,189}

As in GC, HPLC coupled to spectral techniques is necessary for a reliable identification at trace levels. Fast scanning or photodiode array (PDA) spectrophotometers allow the identification of compounds by retention time and spectrum comparison with authentic compounds under the same conditions. HPLC with PDA instrumentation has become common in the residue laboratory.

HPLC, especially with minibore columns, can be coupled to GC. Selected peaks from HPLC can be transferred to GC by valve switching technology and large-volume injection systems. HPLC/GC can, thus, take advantage of the sensitivity and selectivity of the array of detectors developed for GC, including GC/MS, and GC takes advantage of the selectivity options offered by liquid chromatography. Thus, the identification can be supported by two mechanisms of separation and a spectral technique.\textsuperscript{175}

After years of continuous developments and improvements, HPLC/MS coupling has almost reached the simplicity and reliability of GC/MS, at least for bench-top, quadrupole or ion trap mass analyzers. Nowadays the most used interfaces are electrospray and atmospheric pressure CI. Thus, mass spectral confirmation can be obtained also for polar, heat-labile, low volatility, high molecular weight compounds, which include PYR and other new pesticides. HPLC/MS gives CI-type mass spectra which typically have peaks for structural elucidation or confirmation purposes. Both positive and negative ion extraction mode is possible. The choice between positive and negative ion mode depends on the compounds to be analyzed. In the positive ion mode the base peaks are normally the protonated forms of the compounds or their adducts with the cations used in the HPLC eluent. The negative ion mode is more sensitive for electronegative compounds and the base peaks are normally the adducts with the
anions used in the eluent buffer. Also, apparatus is available for HPLC/MS that can perform the MS/MS operation.\(^{(190–195)}\)

### 5.3 Thin-layer Chromatography

Adsorption TLC on alumina has been used for OC pesticides.\(^8\) The eluting solvent was \(n\)-hexane or its mixtures with a small amount of polar modifiers, such as DCM or acetone. Detection of OC pesticides on the plates was carried out by spraying a chromogenic reagent (a solution of silver nitrate in 2-phenoxyethanol–acetone) and exposing the plate to UV light. Quantities as low as 5 ng of most OC pesticides can be detected. Separation and identification on silica gel plates have been reported.\(^{(194–195)}\) Although almost superseded by other techniques, in pesticide residue analysis TLC is gaining a renewed interest after the introduction of high-performance thin-layer chromatography (HPTLC) plates and automated multiple development (AMD) with inverse gradient elution, especially in the analysis of environmental samples.\(^{(196–198)}\) Very small bands with reproducible \(R_f\) are obtained so that the separation of a large number of compounds in a single run is possible. Identification can be obtained through comparison of \(R_f\) and UV or fluorescence spectra acquired with spectrophotometric scanners. The quantitation is possible at very low levels and is carried out by peak areas comparison in multiple-wavelength scanning.

Micro liquid chromatography can be coupled to HPTLC by nitrogen-assisted spraying of different portions of the HPLC eluent onto different lanes of the HPTLC plate. Afterward the plate is developed with the AMD mode and each lane is scanned for peak identification and quantitation. HPLC/HPTLC is a powerful identification tool which combines the high resolution power of HPLC and HPTLC with two different mechanisms of separation (for instance inverse-phase HPLC and adsorption TLC) in an orthogonal high peak capacity separation system, particularly suited for polar heat-labile compounds.\(^{(198)}\)

1 INTRODUCTION

1.1 Sources and Uses of Organophosphorus Pesticides

Much concern is being given to the determination of pesticides in the different environmental matrices, owing to the increased number of pesticides detected and to the severe rules imposed by legislation aimed at protecting natural resources. OPPs were introduced on to the market in the period 1945–55, to replace the toxic and persistent organochlorine insecticides, mainly DDT. They represent a family of about 140 different compounds, which are classified in different groups depending on their chemical structure. They are esters, amides or thiols which in general derive from phosphoric or phosphonic acid, where one or more atoms of hydrogen are substituted by organic groups. Depending on the functional groups, OPPs are divided into six groups or families: phosphates, phosphonates, phosphorothionates, phosphorodithioates, phosphorothiolate and phosphoramidate. Table 1 summarizes the chemical structure...

a R = alkyl or aryl groups; X = aliphatic, aromatic or heterocyclic groups.

of each group. Because the P=S bond is the most stable, many OPPs are synthesized with such a configuration. The characteristics of each group of OPPs can vary substantially, and they confer the specificity to react against one type of organism or another. In general terms, the mode of action of OPPs is based on the inhibition of the enzyme acetylcholine esterase of the organisms, which blocks the nervous transmission and produces death normally by respiratory depression. Owing to this specificity and because they are rapidly degraded after application and are rarely accumulated in the trophic chain, OPPs are extensively used to combat different pests. The main uses are in agricultural crop production, industrial activities and in the tertiary sector (domestic use, mosquito and rodent control, greenhouses, cemeteries, aquaculture, golf courses, etc.). In such practices, OPPs are applied as formulations to enhance their effectiveness upon application, absorption, translocation, immobilization and detoxification. Formulations contain additives and adjuvants such as mixtures of surfactants, mineral and vegetable oils, emulsifiers and salts.

1.2 Distribution and Fate of Pesticides

The distribution and fate of pesticides in the environment depends on whether the pesticide is locally applied or is thoroughly spread over large crop field extensions. Local applications are normally performed by manual spraying or from tractor-trailers, and represent the utmost controlled and optimal conditions since only target organisms are eliminated and pesticide spreading and dissipation are limited. Helicopters or aeroplanes are used to spray large extensions, and dispersion and especially volatilization often occur; as a consequence, pesticides can be found in the atmosphere and in areas far away from the focus treatment point. Once the pesticides have been introduced onto the water or soil surface, they can be transported from the point-source by drift, runoff or soil migration. Moreover, their concentration starts to decrease as a consequence of dispersion, volatilization, degradation and lixiviation, among others. The importance of each process greatly depends on the physicochemical properties of each compound, and also on the water and soil properties, the environmental conditions and the applied concentration and mode of application. During the time a pesticide remains in the environment, chemical (mainly photolysis and hydrolysis) and biological degradation can occur, with the subsequent formation of a TP(3) such as oxo derivatives, sulfones and sulfoxides. Moreover, chloro- and nitrophenols have been reported as the main degradation products of many OPPs.(4,5) Parent pesticides can remain in the soil or sediment whereas TPs, which are more polar than the parent compounds, have a higher capacity to lixiviate and migrate through soil and sediment. As a result, TPs have been encountered in places far away from the point of application and contaminating groundwaters.(6) Groundwater pollution represents a serious environmental problem since in many places these waters are used for drinking and irrigation purposes. In addition, it is known that many TPs are more toxic than their parent compounds(7) so that they can produce deleterious effects towards flora and fauna of surface and groundwater and in sediment organisms.

It is impossible to define a unique fate of pesticides and TPs in the environment since distribution, transport, degradation, dispersion, soil retention and lixiviation will depend on the environmental conditions and on the physicochemical properties of each pesticide. Hence it is clear that to assess the environmental impact of pesticides and their TPs, one should consider all environmental matrices (surface waters, groundwater, soil, vegetables and fruits, atmosphere, etc.). The following section is intended to summarize the most important physicochemical parameters of OPPs and the role they play under environmental conditions.

1.3 Physical and Chemical Properties

OPPs have characteristic chemical structures which confer different physicochemical properties. For instance,
polarity, water solubility, vapor pressure, water–octanol partition coefficient, half-life and acid–base ionization are the main aspects that will influence the persistence or degradation of each OPP in the environment. These physicochemical parameters are generally measured under controlled laboratory conditions, and under similar conditions comparable values are obtained in the literature. Some of these parameters, such as half-life or Ground ubiquity score (mobility index) (GUS), to mention the most important, depend considerably on the specific conditions set up for the experiment and can be measured under either laboratory or environmental conditions. Experiments performed under environmental conditions provide very realistic data which permit one to determine the main degradation processes that occur in natural conditions. However, since they are affected by the temperature, humidity, soil characteristics, water pH, etc., very disparate data are obtained from different authors. The Pesticide Manual\(^9\) and a book on trace determination of pesticides in water\(^9\) list several physicochemical parameters of OPPs. In evaluating the behavior of pesticides in the environment, one should consider the physicochemical properties of each specific pesticide with the objective of establishing the main pathways of the pesticides and the routes of degradation. On the other hand, knowledge of the physicochemical properties of each compound is useful in defining the analytical method for its determination.

Water solubility, defined as the concentration of a chemical dissolved in water, is a parameter that both affects the extraction of pesticides from water, food and soil samples and influences the fate of pesticides in the environment. The water solubilities of OPPs are very variable, with compounds which are almost completely soluble, such as mevinphos (600 g L\(^-1\)), and others which are totally insoluble, such as temephos (0.00003 g L\(^-1\)). In general, distant water solubilities affect the extraction procedure, since the most soluble ones (water solubilities above the grams per liter level) will be difficult to trap and the most insoluble (water solubilities lower than 0.5–1 mg L\(^-1\)) will easily remain adsorbed upon the glassware and other laboratory material, which leads to lower recovery values.

After application of an OPP, this parameter is essential for determining whether a specific compound will remain dissolved in water, is a potential leaker, will be adsorbed on sediment particles or will precipitate at the surface soil. In general terms, it gives a clue to the distribution of a pesticide in the environment. However, this parameter cannot be used solely to predict the distribution of OPPs in the environment.

A parameter related to the water solubility is the water–octanol partition coefficient (reported as a logarithm, usually log\(K_{ow}\) or log\(P_{ow}\)), which is an indicator of the degree of hydrophobicity of a pesticide and its tendency to accumulate in living cells or organisms or to be adsorbed on the organic matter of soils and sediments (humic and fulvic substances). As a rule of thumb, pesticides are classified as apolar if log\(K_{ow}\) values are above 4–5 and polar if they are below 1.5. Between these values, they are considered as “moderately polar”. OPPs with a high log\(K_{ow}\) value (above 4) have a high bioaccumulation potential and therefore they are compounds that if applied at high concentrations can be transferred along the trophic chain. In addition, the soil organic carbon sorption coefficient (\(K_{oc}\)), expressed as cm\(^3\) g\(^{-1}\), is used as an indicator of the degree of attraction and retention of the pesticides in the particles of the soil. The retention will basically depend on the type of soil, and will affect the behavior of the OPP in the field, since an adsorbed molecule can be difficult to solubilize by water, and its availability will decrease. This parameter will also indicate the leaching potential of a pesticide. In general, pesticides with \(K_{oc}\) values below 50 are highly mobile, values between 150 and 500 represent moderately mobile compounds and values higher than 2000 are slightly mobile compounds. The \(K_{oc}\) values of OPPs are very variable, and vary from 44 for mevinphos to 498 for chlorpyrifos.

The solubility, mobility and volatilization of OPPs in the environment will largely depend on their acid–base ionization constants (pK\(_a\)) and whether they are ionized at the pH of each compartment. Volatilization depends on the vapor pressure of each pesticide and on the climatic conditions where the pesticide has been applied, mainly the ambient temperature. OPPs are medium-volatility compounds, with vapor pressures which vary between 0.13 and 7000 mPa. The most volatile compounds will be lost to the atmosphere, especially during application. However, once the OPPs have settled upon the aquatic medium, volatilization will depend on their solubility in water. The Henry’s law constant, denoted \(H\) or \(K_{H}\) (expressed in Pa m\(^3\) mol\(^{-1}\)), is defined as the coefficient between the vapor pressure of a pesticide and its solubility in water, and indicates the volatilization of a compound in solution. To give an example, chlorpyrifos, with a low water solubility (0.0014 g L\(^-1\)) will be easily lost to the atmosphere. It is generally accepted that compounds with \(H\) values below 10\(^{-3}\) Pa m\(^3\) mol\(^{-1}\) will have little tendency to volatilize.

A common way to evaluate the persistence of a pesticides in the environment is the half-life \(t_{1/2}\). The half-life is defined as the time required for a pesticide to reduce the initial concentration by 50%, and it is calculated from the first-order Equation (1):

\[
t_{1/2} = \frac{\ln 2}{k}
\]

\[(1)\]
where \( k \) is the time constant. Half-lives can be calculated under controlled laboratory conditions using Milli-Q water and artificial radiation, simulating environmental conditions,\(^{10} \) or under real environmental conditions. The last case represents the most realistic approach since many different factors and processes play a role in pesticide degradation and dissipation.\(^{6,11} \)

Generally, one takes advantage of phytosanitary treatments to calculate the half-life of a pesticide after it has been applied. The half-lives of OPPs in the environment vary from a few hours to several days, but this value depends on the intrinsic characteristics of each pesticide and on the experimental conditions (climatic conditions, microbial activity, soil and water type, etc.).

Another parameter of environmental interest is the mobility index or GUS, which provides a leaching classification depending on the soil half-life and the \( K_{oc} \) value Equation (2):

\[
GUS = \log T_{0.5}(4 - \log K_{oc}) \tag{2}
\]

where \( T_{0.5} \) is the soil half-life of the pesticide. A GUS higher than 2.8 indicates that the pesticide can be considered as a leacher. Values lower than 1.8 indicate nonleacher pesticides.

In general terms, it can be concluded that the stability of OPPs in the environment depend on several parameters, many of them correlated, in such a way that it is difficult to define a unique parameter as responsible for the fate of OPPs in the environment.

### 1.4 Regulations

Nowadays, hundreds of different OPPs are being used for different purposes. Since 1970, authorities have started to appreciate the danger of water pollution and the need to check the water quality to protect natural drinking sources. Strict directives have been set up and monitoring the concentration levels of OPPs and their TPs in water and other environmental matrices is compulsory. The European Union (EU) has elaborated a “Black List” which includes the 132 most toxic substances for the environment.\(^{12} \) Among other families of compounds, 21 toxic, persistent and widely used OPPs are included. These are designated as priority OPPs and are listed in Table 2. Effort is directed at determining these compounds in monitoring programs.

Moreover, the EU Directive on the Quality of Water Intended for Human Consumption (CEC 76/464/EEC) has elucidated maximum permissible levels of pesticides in drinking water which should be below 0.1 \( \mu \)g L\(^{-1} \) for each individual pesticide and that the sum of all pesticides should be below 0.5 \( \mu \)g L\(^{-1} \).\(^{2} \) In surface water, the concentration of pesticides should be between 1 and 10 \( \mu \)g L\(^{-1} \). Moreover, the USNPS has published a list which includes all pesticides and their TPs, mainly sulfoxides, sulfones and oxo derivatives of OPPs, which were detected in US groundwaters and are considered polar, toxic and persistent.\(^{13,14} \) An overview on the use, consumption and regulatory activities and actions of both the EU and USNPS has been described by Barceló.\(^{15} \) Furthermore, a recent EU Directive appeared in 1996\(^{16} \) that expands the number of contaminants to be monitored in surface and waste effluent waters. The objective is to determine the potential toxicity and environmental impact of newly identified substances (e.g. TPs of pesticides and very polar compounds, which are difficult to analyze using conventional techniques). As a result, most countries control the levels of pesticides in different types of waters with the aim of providing ways and solutions to reduce the level of pollutants in surface and groundwaters. To accomplish such a purpose, it is necessary to use analytical methods which permit the

unequivocal identification and confirmation of pesticides along with their TPs in the environment in a quick and reliable way.

This article describes first the different techniques used for the extraction of pesticides in water and food samples, showing the advantages and disadvantages of each, and discussing the parameters which influence the extraction step. Subsequently, an overview of the most common detection techniques used for OPPs is given. This will permit one to evaluate which is the preferred technique according to the chemical nature of each compound, in which cases it can be used and the information that one will gather. The final section consists of a review of the different validation steps that have to be performed to evaluate any analytical technique. This is specially relevant since all techniques have to be validated for qualitative parameters before they can be routinely applied for monitoring purposes.

2 OUTLINE OF THE ANALYTICAL METHOD

In general terms, determinations of OPPs include four main steps: (i) sampling, (ii) extraction and cleanup of the analytes from the sample, (iii) concentration of the analytes and (iv) detection. The sampling step has to be performed so that the sample is a representative part of a whole area, recovery is maximized and sample contamination is avoided. Barceló and Hennion\(^{(17)}\) have reviewed different sampling strategies, which depend on the type of water to be analyzed and on the sample location.

Many different extraction procedures have been described to isolate pesticides from water. Dichloromethane LLE methods have been reported in the literature, covering several groups of pesticides and being also recommended by the United States Environmental Protection Agency (USEPA) through its National Pesticide Survey.\(^{(18,19)}\) As an alternative to LLE, SPE procedures, also known as liquid–solid extraction (LSE), have been implemented in the last few years, and can be performed both off-line and on-line. SPE methods can be easily converted into fully automated on-line systems coupled to high-performance liquid chromatography (HPLC), in brief LC or GC. Such systems, also referred to as pre-column technology, show additional advantages such as lower detection limits (DLs) (for a given amount of water volume preconcentrated) and that sample manipulation is minimized, which is translated to no evaporation losses, no contamination, no need to concentrate the sample, easy automation and use of small amounts of toxic solvents. There is a great availability of sorbents and configurations which permit the efficient trapping of compounds of diverse polarities with the percolation of only 50–100 mL of water. Recently, besides the well-known C\(_{18}\) and polymeric sorbents, immunoaffinity precolumns have appeared as an alternative to preconcentrate selectively the analytes of interest.\(^{(20)}\) To isolate pesticides from food samples, Soxhlet extraction followed by a cleanup step is the most common approach.

As regards to the analysis of pesticides belonging to different classes, the traditional detection technique has been GC using a selective detector such as the nitrogen-phosphorus detector (NPD)\(^{(21)}\) or flame photometric detection (FPD),\(^{(22)}\) among others. Classically, identification of the analytes is done through retention time comparison with a standard solution. Errors and lack of reproducibility can often appear owing to variations in the response of the detector and to retention time shifts. This is specially relevant when GC/NPD or gas chromatography/flame ionization detection (GC/FID) is used, and therefore duplicate analysis using two columns of different polarity, or otherwise the addition of internal standards (added at the beginning of the analysis) or surrogates (preferably a labeled standard added prior to injection), is needed in order to meet quality control (QC) requirements.\(^{(19)}\) The use of GC with MS detection is a valid alternative to confirm the results obtained by other techniques. However, GC-based techniques are not suitable for the analysis of polar, non-volatile and thermolabile compounds, since for these compounds a derivatization step prior to GC analysis is compulsory. The use of two different detection techniques (or the more expensive MS detector) and the inability to analyze both the polar TPs along with the parental pesticides limit the applicability of GC-based techniques for OPPs’ analysis.

LC techniques are preferred for the analysis of organic pollutants since they cover a wide range of polarities and permit the identification of pesticides along with their TPs. Liquid chromatography with diode-array detection (LC/DAD) has successfully been used to monitor OPPs.\(^{(23)}\) The main advantage of LC/DAD is related to its easy use and to the fact that it offers an absorbance spectra that can be used to identify pesticides through spectral comparison. However, limitations arise for nonultraviolet (UV)-absorbing compounds and because of the impossibility of identifying unknown pesticides (e.g. TPs) in real water samples. Moreover, typical problems related to the analysis of surface waters with LC/DAD are the co-elution of two or more compounds and the presence of interferences, mainly due to humic and fulvic material. To overcome these problems, liquid chromatography with mass spectrometric detection (LC/MS) is used. The higher selectivity and the possibility of obtaining spectral information, together with sufficient sensitivity to use it for quantification purposes, are the main advantages
of this technique. LC/MS with a thermospray (TSP) interface\(^24–26\) has probably been the most widely used technique for pesticide monitoring. In general, it produces molecular information and scarce fragmentation. More structural information can be obtained by using filament-on or discharge ionization. LC/MS with a particle beam (PB) interface\(^27\) has also been extensively applied since it offers abundant fragmentation and can be compared with electron ionization (EI) mass spectra. The high DLs and poor reproducibility are the main problems related to this technique. The advent of atmospheric pressure ionization (APCI) LC/MS interfaces has overcome the disadvantages of GC/MS and other LC/MS interfacing devices such as TSP, because they can provide structural information similar to chemical ionization (CI) and very good sensitivity. Electrospray (ESP), ion-spray (ISP) and atmospheric pressure chemical ionization (APCI) have been applied for pesticide monitoring\(^28–30\) and a DL of few nanograms per liter and a linear response range over two orders of magnitude have been reported.

### 3 WATER SAMPLE HANDLING

After application, pesticides are generally found in the environment at low concentrations, generally around parts per billion or trillion (ppb–ppt level respectively). The trace analysis of pesticides in drinking, surface and wastewaters require the preconcentration of pesticides from the water matrix prior to the chromatographic analysis. The preconcentration step, also referred to as sample pretreatment, involves not only the extraction of pesticides from the water matrix but also the isolation or sample cleanup and generally account for the major part of sample analysis. Traditionally the preconcentration of pesticides was carried out by LLE but nowadays there is a general trend to change current LLE procedures to SPE protocols. Both approaches will be discussed below.

#### 3.1 Liquid–Liquid Extraction

LLE is in many cases the sample preparation technique preferred by the environmental analyst because of its extensive implementation in official methods. LLE is based on the partitioning of different components between aqueous solution and an immiscible organic solvent. Most of the current USEPA methodologies for the analysis of priority pollutants, including pesticides, in water samples involve extraction with various solvents such as dichloromethane, either in acidic conditions to avoid hydrolysis of pesticides\(^31\) or at neutral pH,\(^32\) with butyl acetate,\(^33\) chloroform\(^34\) and hexane.\(^35\) Other approaches have been described using ion pair-forming agents by adjusting the pH to a basic value and adding quaternary ammonium salts.\(^36\) The selectivity of LLE depends on the solvent used, extraction pH, ionic strength, water to solvent ratio, number of extractions and the chemical nature and concentration of the analytes. However, LLE has some drawbacks, e.g. it requires large amounts of generally toxic and inflammable organic solvents, emulsions can be generated and further cleanup is often necessary. The procedure is tedious and it involves considerable sample manipulation, which may lead to losses during the concentration step and result in many cases in poor recoveries and bad reproducibility, with the risk of sample contamination. In addition, evaporative losses may occur during removal of the large solvent volumes, thus making the analysis inaccurate and scarcely reproducible. Moreover, its automation requires the use of expensive robots. Hence there is a general trend to change current LLE procedures to SPE protocols.

#### 3.2 Solid-phase Extraction

SPE has been successfully applied to extract and store pesticides from environmental water matrices and as a cleanup procedure for sediments and food samples.\(^37\) The procedure is based on the use of an adsorbent material which is capable of selectively retaining the pesticides from the matrix. Briefly, the mode of action consists in percolating the sample through the sorbent where the pesticides are retained; subsequently, the pesticides are selectively eluted with an organic solvent. Nowadays there exist a wide variety of SPE methods, which may be divided into off-line and on-line (or precolumn technology) methods. The chemistry and principles of these two approaches are identical. The method involves different steps: (i) washing the sorbent with an organic solvent, often the same solvent as will be used for the elution step; (ii) activation of the sorbent (wetting) with a water-miscible solvent (normally methanol or acetonitrile); (iii) removal of the excess of solvent with pure water; (iv) percolation of the water sample; (v) removal of interferences (cleanup) by flowing water or solvent through the sorbent bed at a high flow rate; and (vi) elution of trapped analytes with a selective solvent, normally compatible with further chromatographic detection system. The different SPE procedures will be described in detail.

#### 3.2.1 Off-line Solid-phase Extraction Methods

In off-line SPE methods, the water sample is percolated through the sorbent bed which is packed in a disposable cartridge or enmeshed in a membrane extraction disk. Samples can move through the sorbent bed by gravity or by application of a positive (syringe) or negative (vacuum manifold) pressure. In general, off-line practices
are well accepted owing to the large variety of packing materials available, C₈, C₁₈, polymeric phases and graphitized carbon black (GCB) being the most common, with different sizes and volumes, which allows great operational flexibility. In the cartridge format, 30 mg–2 g or more of sorbent (normally of 40–150-µm particle size) are usually packed in a polypropylene, Teflon or glass syringe to avoid sample contamination. The off-line procedure using cartridges is illustrated in Figure 1 and consists in conditioning the sorbent, application of the sample and elution. When cartridges are used, the sample normally moves at flow rates of 5–10 mL min⁻¹ to avoid the formation of preferential channels in the sorbent bed that could reduce the adsorption of the analytes towards the sorbent. After sample application, the sorbent is washed with water or solvent to remove impurities, then dried for 5–30 min to displace the excess of water or solvent. Depending on the application, especially if GC analysis is performed, complete drying of the sorbent (under vacuum or with nitrogen) is required before proceeding to the elution step. This drying step may enhance losses of more polar and volatile compounds. The trapped analytes are eluted with 5–20 mL of solvent, generally methanol, acetonitrile, dichloromethane, ethyl acetate, hexane, etc., or mixtures of those, which are applied in two or more steps. A common practice to enhance recoveries is to let the elution solvent soak the sorbent for several minutes before elution. After elution, the excess of elution solvent is evaporated either by rotary evaporation or under a gentle stream of nitrogen to a final extract volume of 0.1–1 mL, depending on the initial concentration of pesticides. A mild evaporation process is usually recommended and dryness should be avoided to prevent important analyte losses. From this extract, an aliquot is injected into the chromatograph.

Application of SPE cartridges for OPPs extraction include the use of Sep-Pak C₈ and C₁₈. XAD resins have been used for extraction and stabilization of pesticides from water. However, this sorbent needs an extensive cleanup prior to the preconcentration step.

The main advantages of using cartridges is that manipulation, solvent disposal and analysis time are reduced in comparison with conventional LLE techniques. Percolation of water samples can be done manually, but nowadays automated devices such as the ASPEC XL from Gilson (France) or the Zymark system (USA) permit the automation of the technique, making it useful for routine analysis. In environmental applications, it is interesting to obtain high enrichment factors so that one can achieve high sensitivity. This can be accomplished with off-line SPE, since there is a great choice of SPE sorbents, with different capacities, and therefore high sample volumes can be percolated. Prior to SPE, surface water samples have to be filtered through 0.45 µm filters to remove sample particles and to avoid clogging of the SPE cartridges. However, filtration may result in poor recoveries of the most apolar compounds, such as temephos, trifluralin and others, which, being preferentially adsorbed on particles, are removed from the aqueous sample together with the particles. In SPE, the extraction efficiency depends on the type of water matrix concerned. In general, drinking or groundwaters produce better recoveries and DLs, since the amounts of interferences are very low. In contrast, when preconcentrating surface or wastewaters, impurities are also preconcentrated, so that worse quality parameters are achieved.

An alternative to off-line SPE with cartridges is the use of Empore extraction disks and Speedisks (Baker, The Netherlands), where the sorbent particles are meshed in Teflon fibrils to form strong sheets or

---

**Figure 1** Off-line SPE process using SPE cartridges. The procedure includes (1) conditioning of the precolumn, (2) sample loading or preconcentration step, (3) elimination of the interferences and (4) elution of the analytes. (Reprinted from 'Handbook of HPLC' eds. E. Katz, R. Eksteen, P. Schoenmakez, N. Miller, with permission of Marcel Dekker Inc.)
membranes which can be used in standard filtration devices. Since the channeling phenomenon does not occur in the disk format, higher sample flow rates can be applied in comparison with cartridges. The main drawback is that automation is not straightforward. Recently, a new disk format has appeared on the market, the Speedisk, and it is provided with, in addition to the active sorbent, a mesh which acts as a filter and, therefore, filtration and extraction are performed in a single step. With these disks, the sample flow rate can be increased to 200 mL min\(^{-1}\), which is interesting from the viewpoint of routine analysis of industrial and wastewater samples, which normally contain large amounts of particulate material. The overall conditioning and extraction time using Speedisks is 10 min. Moreover, racks of six positions are available, which means that six samples can be processed simultaneously in 10 min. Barceló et al.\(^{42,43}\) have applied Empore extraction disks in OPPs analysis and more recently Speedisks have been used to extract several pesticides from surface waters.\(^{44}\)

### 3.2.2 On-line Solid-phase Extraction Methods

A different approach for SPE is the use of on-line systems. In this case, the sorbent is packed in a stainless-steel or Teflon cylindrical precolumn, which can be used under pressure, and is connected on-line with LC or GC. Typical on-line methods for extraction of pesticides were described by Nielen et al.\(^{45}\) and Brinkman.\(^{46}\) The set-up is very simple and is illustrated in Figure 2. The water sample containing the pesticides is pumped, via an inexpensive pump, to the precolumn, which is placed at the loop position of a six-port valve. After preconcentration of the water sample, the valve is electrically switched from the preconcentration position to the elution position and the pesticides are desorbed by the mobile phase and are directed to the analytical column where separation will take place. The main advantage of on-line systems is that they can be fully automated, which makes them specially suitable for routine monitoring programs. The Prospekt (Spark Holland, The Netherlands) and OSP-2 (Merck, Germany) are the two systems commercially available for automated on-line preconcentration. The two systems have their own precolumn design, which covers a large variety of packing materials and includes the possibility of elution in normal and backflush modes.

Parameters that can be optimized for on-line SPE are the volume of water to be preconcentrated, the flow rate, normal or backward elution and type of sorbent used. However, in order to achieve optimal performance with on-line SPE, the sorbent of the precolumn should be as similar as possible to the analytical column packing in terms of type of packing, particle size, etc., to avoid band broadening which can appear specially when normal flush elution is used. Owing to band broadening, quantification of on-line SPE samples with direct injection is not advisable and Pichon and Hennion\(^{47}\) indicated a 5% error if quantification of on-line samples was compared with direct injection. Band broadening can be minimized by using a suitable gradient which causes peak compression on the top of the analytical column. The size of the precolumn is also of importance because the elution profile of the analytes should be as narrow as possible, especially at the beginning of the separation, where the high water content tends to cause peak distortion. Precolumns are generally 2 mm long and 2–3 mm i.d., and are packed with 10–60-µm sorbent material which efficiently traps the analytes while precolumn clogging is prevented. This design is adapted for classical analytical columns of 15–25 cm × 0.46 cm i.d.

Recently, a prototype has been developed by Hewlett-Packard where on-line SPE with LC/DAD has been coupled on-line with a filtration device and refrigerated reservoirs. Such a system is controlled by a unique software and it is totally automated, from sample collection and filtration to the final chromatographic analysis.\(^{48}\) This is a useful approach for the routine monitoring of pesticides in situations where it is necessary to control the water quality over a long time (e.g. depuration plants).
An alternative to SPE coupled with LC is the coupling of SPE on-line with GC.\(^{49}\) This system, known as SAMOS GC, includes the preconcentration unit Prospekt (Spark Holland), an HP 6890 gas chromatograph and an HP Chemstation. Interfacing SPE with GC is the most critical part of the system and it includes a retention gap and a retaining column prior to the analytical column. The different interfaces have been discussed by Brinkman et al.\(^{46,50,51}\) SPE with GC has been coupled to flame ionization detection (FID), NPD and MS with an HP 5973 mass-selective detector. In general, the preconcentration of 1–10 mL of river water is sufficient to quantify pesticides at concentrations of 30–100 ng L\(^{-1}\).\(^{52}\)

On-line methods have the advantage that they can be easily coupled to both LC and GC, making these techniques suitable for the analysis of pesticides in water. In relation to these techniques, the use of small precolumns permits the miniaturization and total automation of the preconcentration technique. DLs at the nanograms per liter level and excellent reproducibility can be obtained by using the on-line approach because the entire sample is transferred to the analytical column and losses during sample manipulation are minimized. As a result, degradation studies can be followed without risk of degradation of pesticides during the extraction procedure. An additional advantage is that by using different types of sorbent it is possible to fractionate the extraction of compounds of different chemical classes.

Another methodology designed for a fast extraction and detection method has been developed by Brinkman’s group.\(^{53}\) The technique, known as single short column (SSC), consists in a unique column 3 cm long in which extraction of the analytes is done at the same time as they are separated. These columns are packed with C\(_8\) or polymeric sorbent and differ from that of a conventional analytical column because they have a higher particle and pore size. As a result, a slight separation of the analytes is performed and, upon elution, the analytes are detected. Similarly to conventional on-line systems, this unique column is coupled to the chromatographic system, and after pumping the water through the SSC desorption takes place on passing the mobile phase through the column. However, ideally an MS detector is necessary to achieve selectivity and unequivocal identification. Hogenboom et al.\(^{55,56}\) detailed the application of the method for water monitoring and indicated that it can be used to identify and even to quantify the analytes. The main advantages of the system are its simplicity and that it consists of a cheap method, which is useful as a screening method for samples that, often, contain small amounts or no trace of pesticides.

Similarly to cartridges, disposable SPE precolumns can also be used for the storage of pesticides. Lacorte et al.\(^{53}\) have used the precolumns of the Prospekt (Spark Holland) for stabilizing 19 OPPs extracted from water samples. Table 3 reports the percentage recoveries of selected OPPs after storing the loaded precolumns at room temperature for 1 month, at 4°C for 3 months and at –20°C for 8 months. It can be seen that –20°C is the best option to avoid degradation. The main advantages reported are the easy transport of the sample and the simplicity and low cost of storing water samples.

### 3.3 Types of Sorbent Materials

A wide range of sorbent materials are available today in different configurations. Even though bonded silicas such as C\(_{18}\) or C\(_8\) are still the most commonly used materials for environmental analysis, polymeric sorbents have become a good alternative for the effective preconcentration of moderately to polar organic compounds.\(^{57,58}\) Polymeric sorbents are available from most manufacturers under various trade names such as Envi-chrom, PLRP-S, Lichrolut EN, Isolute ENV, Oasis, etc., the main differences among them being the pore and particle size distribution. Modifications such as acetylation\(^{59}\) or sulfonation\(^{60}\) have a mixed retention mechanism consisting in hydrophobic and ionic interactions which facilitate the trapping of the most polar pesticides and increase recovery values. DiCorcia et al.\(^{61,62}\) described the use of GCB for analyzing phenols, but it has not been widely applied for OPPs.

For the analysis of OPPs owing to excessive retention of
the most apolar compounds. The poor mechanical sta-

tility of GCB has prevented its routine application in
the on-line approach. This problem was solved by the
development of porous graphite carbon (PGC), where
the graphite is immobilized on a silica structure and the
phase is pressure-resistant and shows better stability. In
general, PGC precolumns should be coupled with a
PGC analytical column to prevent band broadening.

Anion exchangers are also applied for the analysis of
very polar analytes which are not trapped using polymeric
phases. Combination of various sorbent materials such
C_{18}, GCB or PLRP-S with an anion exchanger are
useful for extracting analytes of different polarities and
can be used with both on-line and off-line procedures.
Connection of two precolumns can also be used for
sample cleanup, since one adsorbent is used to trap the
analytes of interest while the other retains the matrix
impurities.

Some limitations of conventional SPE materials are
related to their non-selectivity because they are based on
polar and hydrophobic interactions capable of retaining
humic and fulvic acids and other water matrix compounds
and the incapacity of retaining very polar compounds.
These problems have led to the development of new
sorbent materials, which are based on specific interactions
between the target analyte and the sorbent, and have
the property of specifically retaining the analytes for
which they have been designed. Really promising is the
development of different types of immunoaffinity sorbent
(IS) or immunosorbent and molecular imprinted
classic SPE. In the case of IS, by taking
advantage of cross reactivity, trapping capacity and
selectivity, single analytes or families of compounds of
equal chemical nature can be extracted, thus avoiding
matrix interferences. This approach has recently been
applied for pesticide analysis and Pichon et al. and
Ferrer et al. reported the breakthrough volumes of
several herbicides obtained with immunosorbents. So far,
immunosorbents have not been developed for OPPs.

The other newly developed alternative to conventional
SPE is the use of MIPs, which act in a similar
way to antibodies since the interaction between the
analyte and the polymer is also highly selective. In
contrast to IS, MIPs are synthesized chemically. They
consist of synthetic polymers obtained by polymerizing a
monomer with a cross-linking agent around a template
(analyte). The sorbent is packed in cartridge format. The
preconcentration takes place owing to the cavities on the
polymer left after washing the template. These cavities
will selectively bind the target analyte and structurally
related compounds. As in the case of IS, it consists in a
selective preconcentration where no further cleanup step
is required. MIPs have started to be used for analyte
SPE mainly in the pharmaceutical area. The principal
application of MIPs is in areas where a specific recognition
of particular molecules is needed and antibodies are not
available. In these cases, conventional sorbents are not
useful since an efficient cleanup is necessary to avoid
matrix interferences. In environmental applications,
MIPs have been developed for atrazine, which is a well-
known herbicide, as an ideal compound. In this area
of application, only model conditions have been used,
such as preconcentration of distilled water, and the
extraction procedure is still under development, since
the extraction efficiency depends on parameters such
as solvent composition and pH. The development of
MIPs for OPPs is a promising approach which will permit
selective extraction from both water and food samples.

The main advantages of IS and MIPs over conventional
SPE sorbents is that since there is a selective molecular
recognition to capture the target analyte, they permit a
selective extraction of the sample without the need
for further cleanup. Therefore, a high degree of sample
preconcentration and purification can be achieved with IS
and MIPs. Straight benefits will be for samples in which
the impurities co-extracted with a conventional reversed-
phase sorbent interfere in the chromatographic analysis,
e.g. with diode-array detection (DAD), or suppress the
ionization process in the case of MS detection.

3.4 Parameters Involved in Solid-phase Extraction

Owing to the large variety of packing materials, sizes
and formats, the extraction efficiency for both off- and
on-line modes will vary depending on the nature of the
analytes and on the sample matrix. The most
critical parameter in SPE efficiency is the breakthrough
volume, or the maximum volume of water that can be
concentrated upon an adsorbent without producing
losses of a particular analyte. The breakthrough volume
depends on the polarity of each analyte, on its affinity
for a particular type of sorbent and also on the amount
of sorbent, and therefore will vary from pesticide to
pesticide. In on-line methods, breakthrough of the
more polar pesticides is originated by the restricted
size of the precolumns. This does not happen with
off-line procedures since the amount of sorbent is
not a limitation and, therefore, higher breakthrough
volumes are obtained. Different methods for calculating
the breakthrough volumes are described in a review
by Barceló and Hennion and involve the study of
breakthrough curves or empirical estimation from elution
chromatography.

In addition to the physicochemical properties of each
pesticide, the breakthrough volume will also depend on
the type of water. The analysis of environmental waters
gives, in general, lower breakthrough values than the
analysis of drinking water. This is due to the presence of humic and fulvic acids, which can bind organic contaminants and decrease the recoveries since only the dissolved fraction will be enriched. As mentioned by Senseman et al., the type of water can notably affect analytical performance. An important parameter that affects the extraction efficiency is the pH, and the sample pH should be optimized to maximize the analyte recovery and DLs. Acidification of the sample is a common practice in environmental analysis because it can prevent the deprotonation of the most acidic compounds and inhibit microbiological degradation. However, acidification can raise the hydrophobic character of humic material and lead to higher absorption of the humic material into the sorbent. Those analytes which lack a strong affinity for the sorbent will have lower breakthrough volumes since there is strong competition between the analytes and the humic substances. The humic acids appear in the chromatogram as a large unidentified complex matrix (UCM) interfering peak. Humic material can be partially removed from the sorbent by passing a small amount of water through the sorbent bed after percolating the sample. However, it should be taken into consideration that the washing step can lead to a decrease in recovery because when removing humic material analytes will also be removed. Therefore, the water volume should be carefully optimized, especially when working with low breakthrough volume analytes.

4 COLLECTION AND PREPARATION OF FOOD SAMPLES

Owing to food QC and regulations on QA, OPPs have to be monitored in all agricultural food samples before they are introduced to the market. The major input of pesticides on agricultural products is attributed to direct pesticide application for crop protection and contamination through polluted groundwater irrigation. Food poisoning by OPPs in different food matrices has been reported by Lee et al. and Miyamara et al. The literature regarding the analysis of OPPs in milk and cheese, oils and butterfat, vegetables, eggs and grain, among a long list, refers to different extraction procedures. A comparison of several detection techniques was made by Lee and Wylie. The analysis of food samples differs considerably from that of water samples, and will be discussed below.

4.1 Collection of Food Samples

Meaningful residue data in food samples can only be obtained if careful sampling and collection have been performed. Therefore, the sampling plan should be well studied in relation to the type of pesticide considered and the matrix to be studied. The sample should be representative of a whole population, and should be gathered according to the level of pesticides that have to be determined. Special care should be taken during sample collection to avoid nonrepresentative or spoilt samples. The correct procedure is to collect random grab samples of a whole population, mix the grab samples and reduce the sample size to a final laboratory-size proportion. However, the nature of the matrix will influence the sampling plan. The Manual of Pesticide Residue Analysis reviews the sampling procedures for and analysis of OPPs in different types of food. It is established that for homogeneous products, 0.5–1 kg is sufficient for analysis. For products consisting of small units, sampling should be performed depending on the weight of each unit, e.g. 50 units (1 kg) for items of less than 25 g, 30 units (1–3 kg) for items of 25–100 g, 15 units (2–5 kg) for items of 100–250 g and at least 10 units for items larger than 250 g. After collection, food samples should be immediately transported to the laboratory in suitable conditions (normally refrigerated) in order to avoid degradation of the pesticides or spoilage of the sample matrix.

4.2 Analytical Preparation of Food Samples

Upon receipt, samples should be processed immediately, or otherwise stored at 4°C or preferably at −20°C. Before analysis, it is common practise to check the food sample and note the appearance, aroma, possible deposits, etc. All the physical characteristics should be described, which will aid in interpretation of the final result. Moreover, at this stage, impurities such as stones, insects or rotten parts should be removed. The sample should never be washed before processing. The sample should subsequently be weighed and the number of units should be recorded. In some cases, non-edible parts, e.g. stems, peel, leaves and roots, should be removed and the concentration of residues is then established for the weight of the edible portion. In other cases, it is important to analyze the residue levels of OPPs in the outer sample surface. Of course, the proportion of the sample analyzed will depend on the aim of each study.

At this stage, the gross laboratory sample should first be composited in such a way that representative analytical size samples are obtained from it. This step will depend on the type of sample: whenever possible, material should be homogenized, ground and mixed; products consisting of small units should be quartered and two opposite quarters should be homogenized. For large samples units (cheese, melons, etc.) which cannot be homogenized entirely, aliquots should be gathered and finally homogenized. In any case, from the gross laboratory sample it should be possible to obtain several analytical-size samples, from
which one or two will be analyzed and the rest will be kept as a reserve. These samples should be kept at \(-20^\circ\text{C}\) and wrapped in aluminum foil or kept in glassware, to prevent further decomposition or contamination.

Once the sample has been homogenized and mixed, the pesticides should be extracted. Food samples are more complex to analyze than water samples since the former are far more diverse and differ in the matrix composition (presence of fats, sugars, etc.). The Manual of Pesticide Residue Analysis\(^{(45)}\) describes extensively the different methods used to extract OPPs from different types of food matrices. In this section, only the most common extraction procedures will be mentioned. Since for food samples extraction is influenced by the matrix, the application of one extraction method or another will be basically dependent on the type of pesticide to be analyzed (polarity, \(K_{ow}\), volatility, etc.) and on the type of matrix. In contrast to water samples, in most food samples it is often necessary to perform a cleanup step to remove impurities which would interfere or even suppress the analytical determination. For this reason, it is important to use a selective extraction procedure which will maximize sample cleanup and will permit the use of conventional chromatographic techniques for their analysis.

Freeze-drying is a common method for conditioning biota samples for the extraction of pesticides.\(^{(86)}\) Freeze-drying of biological material is used before extracting the pesticides since it destroys cell membranes and thereafter the contact between the cell tissue and the extraction solvent is increased. Soxhlet extraction is the most usual method to extract pesticides from food samples, despite the sample manipulation and tedious work involved. The most common solvents used for this purpose are ethyl acetate,\(^{(32)}\) acetone and methanol,\(^{(87)}\) acetonitrile\(^{(88)}\) and hexane.\(^{(89)}\)

Nowadays, microwave energy is sometimes used to extract various types of organic compounds from sediment and food samples. However, a recent trial to extract 64 OPPs from onions using a microwave oven indicated that extraction and recovery are affected by microwave heating.

Many extraction methods have been developed to extract pesticides from food samples and the application of one or another depends on the food sample matrix. For instance, strong acids or alkalis are used to facilitate the extraction of pesticides from foods with a high lipid content. However, many OPPs are decomposed in such media. As a result, the sample is extracted at neutral pH and the fatty matrix is subsequently removed by a suitable and nondestructive cleanup step, usually column chromatography with silica gel, alumina or Florisil.\(^{(90,91)}\) The last method is that adopted by the USEPA.\(^{(92)}\)

Gel permeation chromatography (GPC) is another cleanup alternative, and can be used with low-pressure chromatographic columns in such a way that it permits the discrimination of compounds depending on their molecular size. Large biogenic compounds, such as lipids, are excluded from the pores of the polymeric material and are eluted before smaller analytes, which are retained in the column pores. The separation mechanism is a combination of size exclusion, adsorption and partition. The prevalence of one mechanism over another depends on the mobile phase and the pore size of the polymeric material chosen. Common elution solvents used in GPC are ethyl acetate–cyclohexane,\(^{(32)}\) acetone–cyclohexane, acetone–light petroleum\(^{(93)}\) and cyclohexane–dichloromethane.\(^{(94)}\) Thirty-nine pesticides (including their major metabolites) were determined in fatty processed food using dichloromethane extraction and GPC with a Biobeads SX3 column and dichloromethane–cyclohexane as eluent, giving recoveries between 51 and 185%.\(^{(95)}\) The same column has been used to clean up carrot extracts, indicating that the high pigment content of samples produced band broadening on the column.\(^{(96)}\) A different approach consisting of accelerated solvent extraction and cleanup with GPC has been used to analyze OPPs, among others, in foods, indicating recoveries from 80 to 90% and precision below 10%,\(^{(97)}\) GPC has been also coupled on-line with GC and has been applied to extract OPPs in olive oil.\(^{(98)}\) Other authors have indicated an efficient extraction of olive oil with acetonitrile, with no need for sample cleanup prior to GC, and reported recoveries ranging from 74 to 118%, indicating that the column efficiency is not affected by co-extracted oil impurities.\(^{(99)}\)

A less common approach for the cleanup of food samples is the use of normal-phase LC, with silica columns and dichloromethane–hexane or dichloromethane–pentane as eluent, giving recoveries between 50 and 185%. However, cleanup consists of matrix solid-phase dispersion, and from cereal flours,\(^{(82)}\) SPE has been used as a cleanup technique to extract OPPs from eggs\(^{(82)}\) and from cereal flours\(^{(102)}\) by using minicolumns prepacked with Florisil. A promising analytical technique to extract OPPs selectively from food samples is the use of IS or MIPs, but application in such matrices is still under development.

Other techniques to extract OPPs selectively without further cleanup consist of matrix solid-phase dispersion, which has been applied to extract OPPs from milk\(^{(103)}\) and oranges\(^{(104)}\) while supercritical fluid extraction (SFE) permits better recoveries of several OPPs in comparison with Florisil cleanup.\(^{(105)}\)
5 GAS CHROMATOGRAPHIC DETERMINATION

5.1 Gas Chromatographic Detectors

GC plays an important role in trace analysis. It is a well-known and widely established analytical technique and it is the official technique adopted by the USEPA (EPA Method 8140). GC coupled to an NPD, FID or electron-capture detector (ECD), atomic emission detector (AED) or pulsed-FPD is still the most common technique for OPP analysis in different environmental samples. The main reasons are the low DLs that can be achieved and high selectivity which permits multicomponent analysis and minimizes the effect of the sample matrix. In general, GC detectors provide a linear range over various orders of magnitude and DLs at the low nanograms per liter level in water and nanograms per gram level in food samples. However, when using these detectors, the USEPA indicate the need to confirm the results by using two different GC columns of different polarity, usually a DB-5 and a DB-1701. The use of different columns solves the risk of co-elution and avoids false-positive determinations in environmental water analysis. Lacorte and Barceló carried out a systematic study with the aim of studying the retention times of 26 OPPs and various TPs in three different capillary GC columns. Another way to confirm the results is the use of GC with MS as the detection technique for both qualitative (it provides mass spectral information) and quantitative purposes. GC/MS has been performed either with the EI technique, positive chemical ionization (PCI), negative chemical ionization (NCI) and tandem mass spectrometry (MS/MS) and has been widely applied for pesticide analysis. Information that can be obtained with GC/MS is summarized below.

5.2 Gas Chromatography/Mass Spectrometry with Electron Ionization

One of the main advantages of GC/MS with EI is the existence of libraries which contain more than 120,000 spectra. EI gives very good reproducibility of the spectral data, even when using different mass spectrometers, so that identification and confirmation of the presence of OPPs in an environmental sample are performed by spectral matching. At the same time, GC/MS gives good sensitivity and can also be used for quantification purposes. EI is normally coupled with quadrupole mass analyzers, but magnetic sectors and ion traps can also be used. Different analyzers can lead to variations in the relative abundances in the EI mass spectrum. Various references with GC/MS data using EI for the analysis of OPPs have been published. EI provides abundant fragmentation of the analytes but molecular weight information is scarce, since the molecular ion species, M⁺, is not always observed. For this reason, the USEPA recommends the identification for one pesticide of at least three different ions. Upon fragmentation, OPPs produce diagnostic or characteristic ions which correspond to the functional group structure of each family of pesticides and permit their identification. Other fragment ions formed correspond to specific ions, and are typical of each compound. An extensive study reported by Wilkins et al. was based on the identification of various OPP compounds by five typical rearrangements, with diagnostic ions corresponding to m/z values of 93, 97, 109, 121 and 125. A more recent study also concerning OPPs, gave information on diagnostic fragment ions obtained by GC/MS with EI as well as compound-specific ions, as indicated in Table 4. Various possibilities of tentative ion identification for the same fragment ion, e.g. m/z 97, 109, 127 and 137, are given. This qualitative information is valuable since it can be used for identifying OPPs and their TPs from complex environmental matrices. It was concluded that (i) diagnostic fragment ions reported in Table 4 usually correspond to a class of OPP compounds. In this sense, m/z at 109 and 125 are base peaks for the dimethylphosphates and dimethylphosphorothioates, respectively. (ii) In some cases, diagnostic fragment ions depend on the type of molecule and it is possible that two ions with different nomenclature can correspond to the same compound.

compounds will have an ion at the same m/z value but have different chemical compositions (indicating different families). This is the case of m/z 109, corresponding either to (CH₃O)₂PO⁺ (methylphosphates), (C₂H₅O)OHPO⁺ (ethylphosphates) or (C₂H₅O)PSH⁺ (ethylphosphorothioates). The rearrangement ion at m/z 97 usually corresponds to (OH)₂PS⁺ (phosphorothioate), but in the case of phosphorodithioates it corresponds to (SH)₂P⁺.

It is therefore useful to have the chemical structures of the different compounds since some of the fragment ions can then be predicted. (iii) The abundance of molecular ion species M⁺ increases with its ability to sustain a positive charge and is related to the ionization energy, which is lower for S than O. Examples of this case include parathion-ethyl and fenitrothion, which show higher relative abundances of M⁺ as compared with the oxo derivatives. (iv) The chlorinated compounds exhibit as main peaks the corresponding fragment ions with chlorine losses. (v) Specific fragments which are typical of some compounds are also observed, e.g. McLafferty rearrangement involving proton extraction by an oxygen of the nitro group indicating the presence of CH₃ adjacent to an NO₂ group, as for fenitrothion and fenitrooxon.

The sensitivity of GC/MS can be increased by one order of magnitude by using selected ion monitoring (SIM), where only a few ions are recorded. By selecting appropriate diagnostic and specific fragment ions of OPPs, quantitation of environmental samples can be performed at the parts per billion level and the technique can be routinely applied in monitoring studies. In general, the use of higher m/z values is preferred since better selectivity is obtained and matrix interferences are minimized.

### 5.3 Gas Chromatography/Mass Spectrometry with Chemical Ionization

GC/MS with either PCI or NCI consists in a soft ionization technique which gives molecular weight information that EI spectra rarely give. In CI a reagent gas, normally methane, isobutane or ammonia, is used for the ionization process. CI mass spectra are not as reproducible as with EI, since many parameters are involved in the ionization process. The reagent gas used, the reagent gas pressure applied and the source temperature affect the fragmentation pattern and the sensitivity. It is for this reason, and because mass spectra are very much dependent on the instrument type, that there are no libraries of spectra available for CI mass spectra. Of the two modes of ionization, NCI is more selective and sensitive than PCI and EI and it is the preferred option for the determination of OPPs with electron-withdrawing groups (nitro- or chloroaromatic groups). The molecules of the so-called parathion-like structure offered high sensitivity under the negative ion conditions owing to the presence of an aromatic moiety which is accompanied by a nitro group, thus forming a kind of pseudoacid by electron attachment which stabilizes the negative charge.

When this aromatic moiety contains other electron-withdrawing groups, e.g. chlorine atoms, the stabilization of the negative charge and sensitivity are also enhanced. The sensitivity can be increased by two orders of magnitude compared with GC/MS with EI. Table 5 lists the diagnostic ions of the different OPPs, which are characteristic of the different chemical groups. The following general remarks can be made. (i) The diagnostic ions formed under NCI are, in many cases, the base peaks of the analytes and, in some cases, the only spectral information obtained. This is a typical characteristic on MS with NCI of OPPs, so their unequivocal identification should always be performed in combination with the retention time. (ii) The formation of M⁺⁻ has a 100% relative abundance for the OPPs of the so-called parathion group, and compounds having an aromatic moiety (with the exception of chlorinated OPPs). This is due to the fact that M⁺⁻ is fairly stable under NCI conditions when an aromatic moiety exists in the molecule, and is even more important when a nitro group is present. (iii) The chlorinated OPPs with an aromatic moiety have intense or base peaks corresponding to losses of Cl, such as CH₃Cl or HCl, owing to the facility of such processes under NCI conditions. (iv) The formation of thiophenolate versus fenolate ions for compounds such as parathion, fenitrothion, coumaphos and fenchlorfos is due to their stronger acidity in the gas phase and there is a transfer from the aromatic moiety from the oxygen to the sulfur atom.

Complementing GC/MS with EI and NCI is useful in environmental analysis because some compounds will give a better response under one type of ionization mode whereas others, with different structural characteristics, give a better signal under the another. Moreover, the use of two GC/MS techniques is a means of confirming the presence of pesticides in environmental matrices.

and, more importantly, it permits the unequivocal identification of TPs that might be formed in environmental samples. Such an approach was used to follow the degradation kinetics of fenitrothion after being applied in the environment for eradicating the crab *Procambarus clarkii*. Fenitrooxon, the \( s \)-methyl isomer of fenitrothion and 3-methyl-4-nitrophenol were detected as the main TPs of fenitrothion by GC/MS with both EI and NCI, and trace levels were found in water 4 days after application. Such techniques permitted the concentration of fenitrothion to be monitored for 7 days, which was useful for determining the half-life. Under the field conditions and at water temperatures of 10–13 °C, the half-life of fenitrothion was estimated to be 13 h. The evolution of the levels of fenitrothion under environmental conditions are shown in Figure 3. Figure 4 shows the degradation pathway of fenitrothion under these conditions. It can be concluded, therefore, that GC is a powerful technique in environmental water analysis, owing to the separation efficiency, the wide availability of detectors, including MS, and the possibility of performing degradation studies. However, one of the limitations of GC/MS is that polar, non-volatile or thermolabile pesticides cannot be directly analyzed without a derivatization step. Derivatization increases sample manipulation and time of analysis and introduces new sources of errors. For such reasons, there is a general tendency to switch to LC, which can overcome the aforementioned limitations.

**Figure 3** Evolution of the levels of the concentration of fenitrothion [plotted as logarithm of concentration versus time, giving both measured values and calculated values, according to the first-order rate Equation (1)] and its TPs after application of fenitrothion in the field at a concentration of 200µg L\(^{-1}\). ### 6 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

HPLC has become popular for the analysis of compounds that are not amenable to GC. The increasing development of HPLC techniques has led to the sensitivity needed to meet EU legislation for the analysis of polar pesticides in surface and food samples. In HPLC the mobile phase flows through the stationary phase and separation of the analytes takes place owing to the interactions between the solute, the mobile phase and the sorbent. In environmental applications, reversed-phase chromatography is the most common separation mechanism used in HPLC, although other approaches such as adsorption, ion-exchange and size-exclusion chromatography (SEC) can also be used. Stationary phases used in reversed-phase chromatography are alkyl- or phenyl-bonded silicas, polymeric materials or carbon-based sorbents. By using methanol, acetonitrile, water and tetrahydrofuran (THF) or combinations of them, it is possible to separate pesticides over a wide range of polarities, including their TPs. Since HPLC techniques can be applied to non-volatile, thermolabile and polar compounds, it is becoming the favored technique for OPP analysis. An additional advantage over GC is that on-line SPE and postcolumn systems are easily compatible with
LC. This feature combines the extraction step and chromatographic analysis in a single, totally automated step, which is an interesting property from the viewpoint of routine analysis and reduction of sample manipulation.

HPLC can be coupled with various types of detectors, such as UV and fluorescence detectors, DAD and mass spectrometers, which make the techniques robust and adapted to each experimental requirement. Coupling LC with MS is not as obvious as with GC/MS, since the mobile phase has to be eliminated before entering the mass spectrometer and at the same time ions have to be generated. A book\(^{119}\) has been published that provides an overview of the different LC/MS applications for environmental analysis. Several interfaces have been designed to overcome the problem: trace enrichment (PB and moving belt) and nebulization (TSP and API interfaces). Trace enrichment interfaces have the advantage that they can provide EI mass spectra but their application in the environmental field has been reduced owing to their low sensitivity and poor reproducibility. For this reason, these interfaces will not be treated in this article and all the discussion will be focused towards DAD and nebulization devices.

### 6.1 Liquid Chromatography with Diode-array Detection

Recent developments in DAD permit the achievement of DLs in the nanograms range and a UV visible spectra can be recorded so that the analytes can be identified by spectral comparison against a standard previously injected. Pesticides susceptible to absorbing UV radiation are those which present a suitable chromophore and in general they present a typical UV spectrum with a maximum between 230 and 280 nm. Modern instruments can monitor between 190 and 800 nm, at a rate up to one spectrum per second, which permits very good spectral resolution. Moreover, most software includes the peak purity analysis of each detected compound which indicates potential co-elution problems with another pesticide or with matrix interferents. These two characteristics are very useful since it is possible to distinguish compounds of the same family that can have very similar UV spectra. At the same time, pesticide TPs have spectral similarities with their parent compounds, and there is only a slight shift in the absorbance spectra. By setting the acquisition parameters to obtain good resolution, it is possible to identify chemically related compounds. This characteristic makes HPLC with DAD the most common detection method for pesticide analysis in water and food samples. Peak identification with LC/DAD is usually carried out by means of the retention time in comparison with a standard and by spectral matching through a library search, an option which is nowadays included in most software. Selectivity can be enhanced by choosing an appropriate UV wavelength which permits the identification and quantification of pesticides with very close retention times and even a reduction in the contribution of matrix interferences. Therefore, it is recommended to perform quantitative analysis at the wavelength which provides better calibration adjustment. Peak purity analysis is also important to achieve good accuracy.

A review describes the applications of LC/DAD and other detection techniques for the determination of polar pesticides and related compounds in aquatic samples.\(^{120}\) Other papers report the use of LC/DAD to monitor OPPs in surface waters, either using on-line SPE\(^{121–123}\) or offline methods.\(^{124}\) The main drawbacks related to DAD are due to the poor selectivity when analyzing complex environmental samples which contain large amounts of humic and fulvic material or other interferents. At this point, sample pretreatment should be optimized, especially the cleanup step to remove interferences which appear especially when working at low wavelengths. At the same time, DLs are increased by this matrix effect.

### 6.2 Liquid Chromatography and Mass Spectrometry with Thermospray Interface

Liquid chromatography coupled to mass spectrometry with a thermospray interface (LC/TSPMS) has been widely used to determine organic contaminants in water matrices\(^{125,126}\) and has been adopted by the USEPA (Method 8321)\(^{127}\) for the analysis of OPPs in different types of water matrices. The LC/TSPMS interface consists of sample nebulization and ionization through a heated capillary. It is a soft ionization technique which produces molecular peak spectra and scarce fragment ions. The spectral pattern depends on the additives added to the mobile phase, which are mainly ammonium acetate or formate. Ionization is due to gas-phase protonation reactions between the analyte and the ammonium.\(^{26,128}\) The main disadvantage of LC/TSPMS is that it gives poor structural information. This can be solved by using filament-on or discharge assisted ionization which generates solvent mediated ionization similar to direct TSP ionization (without additives) and sensitivity is enhanced.\(^{129}\) The use of liquid chromatography coupled to tandem mass spectrometry with a thermospray interface (LC/TSPMS/MS) is the best choice to enhance fragmentation of quasimolecular ions\(^{130}\) and it offers collision-induced dissociation (CID) spectra and is used for both identification and quantification purposes. However, this is an expensive instrument which cannot be afforded by most laboratories.

Ion formation in TSP in the positive ionization (PI) mode generates \([M + H]^+\) and the ammonium adduct \([M + NH_4]^+\) as base peaks for pesticides, depending on the proton affinity of each compound. In the negative ionization (NI) mode, \([M – H]^–\) or acetate or formate adducts are formed. The NI mode is more sensitive and
selective for the analysis of electronegative compounds, such as chlorinated OPPs.

The characterization of several pesticides by LC/TSPMS in PI and NI modes using filament-on ionization was detailed by Lacorte and Barceló, who remarked that little or no fragmentation is observed for many of the pesticides. This represents a drawback since the identification of unknowns in environmental samples (e.g. TPs of OPPs) becomes difficult. The requirement set by the USNPS, in which at least three different ions are needed to confirm unequivocally the presence of a pesticide in a real water sample, generally is not accomplished by using LC/TSPMS. Rather than compound identification, LC/TSPMS is more useful for target compound analysis. Under full-scan conditions, instrument detection limits (IDLs) are around 1 ng for pesticides.

Sensitivity can be enhanced by coupling SPE on-line with LC/TSPMS. This approach has been used to quantify and identify OPPs and their TPs in environmental matrices. On-line SPE coupled with LC/TSPMS and on-line SPE coupled with LC/DAD have been used to follow the degradation of several OPPs in seminatural conditions (river water spiked at a low concentration level and exposed outdoors for 4 weeks). The half-life measured as $t_{1/2} = \ln 2/k$ indicated that pesticides persisted in such conditions for 6–12 days. However, when degradation occurred, confirmatory analysis of pesticide TPs was carried out by means of MS detection with a TSP interface. The oxo derivatives of chlorpyrifos-methyl, diazinon, isofenphos, pyridafenthion and temephos were detected 4 weeks after sunlight exposure. In general, the oxygen analogues could be identified since they followed the same adduct formation as the parent pesticide and eluted before the parent compound.

Figure 5(a–c) shows the LC/DAD and LC/TSPMS chromatograms of a water sample spiked with chlorpyrifos-methyl and analyzed after 4 weeks. Whereas LC/DAD detected chlorpyrifos and a TP not unequivocally identified, LC/TSPMS in the PI and NI modes confirmed the presence of chlorpyrifos ($m/z$ 323), its oxo derivative ($m/z$ 324) and 3,5,6-trichloro-2-pyridinol ($m/z$ 198). Chlorpyrifos and the two TPs identified exhibited losses of chlorine atoms and proton abstraction, similarly to the parent compound. The toxicity of 3,5,6-trichloro-2-pyridinol is greater than that of chlorpyrifos, with EC50 values of 18.6 and 46.3 µg mL$^{-1}$, respectively, calculated with the Microtox system. Also, it has been reported that this compound is toxic to soil microorganisms and results in less mineralization and therefore enhanced persistence of chlorpyrifos in soil. This example indicates the importance of analyzing TPs and the need to include them in the analytical methods.

Although LC/TSPMS affords some structural information, often more fragment ions are needed for confirmatory purposes. LC/TSPMS/MS techniques or API interfaces can solve the problem, since they can produce spectra by CID. An additional drawback of LC/TSPMS is the high intraday signal variations, which lead to poor reproducibility. For these reasons, many laboratories tend to switch to the new API interfaces which nowadays is the preferred option for the analysis of pesticides in environmental samples since it is a more robust technique. API includes several interfaces, i.e. ESP, the high-flow pneumatically assisted ESP, commonly named ISP, the heated pneumatic nebulizer (HPN) and APCI. The main

\[ \text{Figure 5 Reconstructed ion chromatograms obtained with on-line LSE with LC/TSPMS with (a) PI and (b) NI mode of ionization of an Ebre river water sample spiked with chlorpyrifos-methyl at 50 µg L}^{-1}, \text{and analyzing the water sample 4 weeks after spiking. advantage of these interfaces is their higher sensitivity for OPP analysis compared with TSP or PB.\textsuperscript{135–137}

### 6.3 Liquid Chromatography and Mass Spectrometry with Electrospray/Ionspray Interfaces

Electrospray/ionspray (ESP/ISP) consists in applying a voltage to a capillary that ionizes the solvent extract with the pesticides, which emerge from the capillary as a spray. This spray contains microdroplets which are positively or negatively charged, depending on the difference of potential between the capillary and the counterelectrode. In the desolvation chamber, the droplets undergo ion evaporation and ions escape to the gas phase. Such ions are then focused towards the quadrupole of the mass spectrometer. In electrospray/i onspray mass spectrometry (ESP/ISPMS), 90\% of the ions are formed in solution and at atmospheric pressure. The main advantage of ESP/ISP techniques is that no heat is applied to ionize the samples, eliminating thermally assisted degradation, as happens when using a GC or TSP interface. This allows the LC/MS analysis of thermolabile analytes such as trichlorfon,\textsuperscript{138} which is a compound that has been shown to suffer thermal degradation under LC/TSPMS caused by the probe tip and gas-phase temperatures higher than 200°C. The major differences between these two interfaces is that in ESP only 10–80 µL min\(^{-1}\) can be directed to the source, whereas in ISP flow rates from 300 to 1000 µL min\(^{-1}\) can be applied. A few applications using ESP have been undertaken for OPPs.\textsuperscript{28,139} In ESP it is necessary to use syringe LC pumps, or otherwise when using conventional LC pumps a splitting device should be used.\textsuperscript{140} In ISP, higher flow rates (up to 1500 µL min\(^{-1}\) in the new-generation interfaces) can be handled; a gas flow, normally nitrogen, is applied in the interface and acts as a nebulizer. After nebulization of the liquid, a heated drying gas is applied countercurrent and droplet evaporation is facilitated by breaking the analyte–solvent clusters at the desolvation chamber. The drying gas also prevents clogging of the sample orifice. With ISP, ions emerge from the capillary owing to the simultaneous action of the nitrogen and the capillary voltage set at 2–4 kV.

Ion formation in ESP/ISP is due to the evaporation of ions from charged droplets, which results in ions with very little internal energy and, therefore, molecular or quasimolecular ions are formed with little or no fragmentation. To enhance fragmentation, an extraction potential of 10–200 V, depending on the particular design of the interface, is applied at the extraction cone. This potential focuses the spray towards the sample orifice and into the high vacuum of the mass spectrometer. An increase in this potential accelerates the ions and the collisions between them induce fragmentation via CID. In some cases, an increase in the cone voltage can lead to a decrease in sensitivity. Therefore, careful optimization of the cone voltage is required and generally a compromise between structural information and sensitivity has to be achieved.

In ESP/ISPMS, methanol or acetonitrile and water are generally used as mobile phase. When working in PI and at low extraction voltage (e.g. 20 V), the formation of [M + H]\(^+\) and [M + Na]\(^+\) is favored and these are generally the base peaks. The generation of [M + Na]\(^+\) is more common when methanol is used in the mobile phase since the Na\(^+\) ions are due to impurities in the methanol solution. On increasing the extraction voltage, fragmentation occurs at the expense of [M + H]\(^+\) ion and results in diagnostic or compound-specific fragment ions.

ISP under PI permitted DLs at the picogram level to be achieved for selected pesticides. Sensitivity problems for the parathion group (parathion-methyl, parathion-ethyl, fenitrothion and fenitrooxon) were noticed when using ISP or conventional ESP.\textsuperscript{28} The ionization of these compounds under ESP conditions offers problems and generally it is difficult to achieve low nanograms per liter DLs in water samples. In general, the repeatability and the long-term reproducibility (\(n = 9\)) for OPPs vary from 12–17 to 22–30\%, respectively, on injecting 1 ng of each compound, which is better than that obtained by using LC/TSPMS.

A remarkable fact is that typical diagnostic ions of OPPs formed in liquid chromatography coupled to electrospray/i onspray mass spectrometry (LC/ESP/ISPMS) are similar to those in EI. The formation of diagnostic ions at \(m/z\) 109, 110, 125 and 141, to mention some, permits the identification of each family of pesticides. This is an important feature, which is not accomplished by TSP, and therefore these techniques can be used for the identification of pesticides and their TPs in environmental samples. Moreover, more structural information is obtained at 40 V or higher voltages (compared with 20 V) and permits the easy identification of nontarget pesticides in environmental samples.

The use of ISP in NI has been scarce owing to the poor ion stability and the problems of electric (corona) discharge, presumably caused by electrons emanating from the sharp edges of the ISP capillary needle held at a few thousand volts negative relative to a counter-electrode. The signal instability of electrospray ionization (ESI) can be reduced by adding chloroacetonitrile to the LC eluent, which acts as an electron scavenger, and there is a suppression of the electrical (corona) discharge phenomena leading to a stable ESI with finer charged liquid droplets. Nevertheless, the improvement in ion stability is obtained at the expense of sensitivity (one order of magnitude less) owing to the [M + Cl]\(^-\) adduct ion formation and to the higher cluster ions intensity. Since the major analytical requirement of environmental analysis is to achieve a low DL, chloroacetonitrile is not commonly used.
6.4 Liquid Chromatography and Mass Spectrometry with Atmospheric Pressure Chemical Ionization

In APCI, the column eluent is pneumatically and thermally nebulized into an atmospheric pressure ion source. The APCI technique differs from ESP and ISP in that the spray is generated as a result of applying nitrogen gas and heat at the interface. The spray, which contains the mobile phase and the analytes, is subsequently ionized at the nebulizing chamber after applying a corona discharge of 2–4 kV. The analytes are ionized by gas-phase ion–molecule reactions (e.g. proton transfer). The ions formed, together with solvent vapor and nebulizing gas, are sampled towards the sample cone and into the mass spectrometer.

The main advantages of liquid chromatography coupled to mass spectrometry with atmospheric pressure chemical ionization (LC/APCIMS) over ESP/ISP is that ions do not have to be formed in solution and, therefore, compounds with a wider range of polarities and physicochemical properties can be determined. Another advantage is that more fragmentation is obtained with APCI than ESP/ISP and that sodium clusters rarely appear. As heat is applied in addition to pneumatic nebulization, some OPPs can be determined with APCI whereas they gave no signal under ESP/ISP. Moreover, in APCI, higher flow rates can be handled (up to 2 mL min$^{-1}$), which makes it easy to couple with conventional columns and with SPE switching techniques. In APCI, no buffer addition is required and, in contrast to TSP, no significant differences in sensitivity are observed when working at different ratios of water and organic modifier.

From the practical point of view, there are two main parameters to be optimized in APCI: the corona discharge voltage and the cone extraction voltage. For the corona discharge, a voltage between 2.5 and 3 kV is usually chosen, as at lower discharge voltages weak ionization is achieved and above 3 kV the ionization efficiency decreases dramatically. Similar to the ISP interface, by raising the cone voltage structural information can be obtained via CID. The advantage of APCI techniques is that analytical parameters can be varied to gain both in structural information and sensitivity. The pressure of the nebulizing and drying gas basically affects sensitivity. A study$^{[141]}$ has been published on the probe temperature and extraction voltage effect of the APCI interface on the fragmentation and sensitivity of several OPPs. Whereas the interface temperature has a major role in sensitivity and does not affect fragmentation, an increase in the extraction voltage produces more fragmentation, at the expense of sensitivity. It was found that at a 30 V extraction voltage, the best sensitivity was obtained for the majority of the OPPs studied, whereas 40 V produced the highest fragmentation, giving in most cases fragmentation patterns similar to those obtained with MS/MS. By increasing the cone voltage to 60 V, pseudomolecular ions of pesticides underwent strong fragmentation to the point that only diagnostic fragment ions were present in the CID spectra.$^{[141]}$ Pesticides of the parathion group underwent strong fragmentation at low extraction voltages, giving fragment ions with low $m/z$ as base peaks. For these pesticides, there were no differences in the formation of fragment ions under cone voltages of 20 and 40 V, probably because an extraction voltage of 20 V was sufficient to fragment the molecules. Table 6 indicates the fragment formation under these conditions.

n.i. = not identified.
ions of several OPPs obtained by LC/APCIMS in the PI mode of operation with extraction voltages of 20 and 40 V. It can be observed that the fragmentation pattern differs in the two conditions and, in general, fragment ions of lower m/z values are formed at a 40-V extraction voltage.

Previous studies on OPP analysis with LC/APCIMS include those of Kawasaki et al., who obtained structural information under APCI conditions and DLs varying between 2 and 50 ng under SIM conditions. The optimization and validation of on-line SPE with LC/APCIMS for OPP analysis has been performed by Lacorte et al., who report DLs at the low nanograms per liter level and good recovery and reproducibility values. Figure 6(a–c) shows a typical chromatographic profile of a 100-mL groundwater sample spiked with pesticides at 1 µg L⁻¹ and analyzed under full-scan and SIM in PI and NI modes of ionization. An interesting feature of on-line SPE with LC/APCIMS is that it can be operated under full-scan conditions as an “alarm” system to detect organic contaminants in water samples, since pesticides are found in natural waters at levels between 1 and 10 µg L⁻¹. In general, DLs of OPPs are around 500 ng L⁻¹ in full-scan and 1–60 ng L⁻¹ in the SIM mode. The excellent sensitivity, even in the full-scan mode, combined with the abundant structural information provided by the APCI interface makes the technique suitable for the screening of pesticides in environmental samples in the parts per trillion to billion range. The APCI interface can also be used for structural elucidation studies. Several TPs of temephos and fenthion were identified by increasing the extraction voltage of the APCI interface. At a 40-V extraction voltage, oxo analogues, sulfoxides and the isomeric forms of the above-mentioned pesticides were unequivocally identified. This means that in the near future, this technique can be implemented in routine work for the analysis of real water samples, since it can detect both parents and TPs of pesticides at the nanograms per liter level. However, more research is needed on the characterization of oxo analogues and other metabolites before optimal analytical conditions can be defined.

LC/APCIMS under NI normally generates [M – H]⁻ ion or specific fragment ions as the base peak. The use of the NI mode permits the detection of most electronegative compounds and better selectivity and sensitivity are obtained. However, many OPPs can undergo strong fragmentation, even at a 20-V extraction voltage, and produce in some cases a single ion, which is often a diagnostic ion, so that compound elucidation is difficult.

In summary, future trends will lead to the more extensive use of API interfaces for environmental applications owing their high sensitivity and the possibility of obtaining structural information. However, the main operational problem with APCI and in general all API
interfases arises from the high cleaning requirements of the sample cone and skimmer assembly, especially when dirty water samples are processed. However, it should be remembered that this is a common problem with most of the LC/MS interfaces currently available. To achieve maximum sensitivity in API techniques, the system should be calibrated very accurately, and therefore it is essential to have a clean interface. In API interfaces, the system response should be checked after every cleaning step, but even with a clean interface, reproducibility values above 25% are common. Better values are obtained if an internal standard is used.

7 VALIDATION OF ANALYTICAL METHODS

As a result of variations in the results reported by various laboratories, method testing, based on repeatability, reproducibility and calibration data, should be done routinely to evaluate the performance of an analytical method. Any analytical method should be precisely developed to provide reliable quantitative results. Therefore, validation becomes a key issue before method approval and implementation can be done. Any analytical method should provide statistical documentation of its capacity for rendering accurate results. In environmental chemistry, the achievement of an accurate determination is a challenge since (i) the analytes of interest are often at a very low concentration level, normally in the parts per trillion to billion range, (ii) environmental matrices can be very diverse and complex, from drinking and groundwater samples, which represent the easiest matrix, to surface or wastewater, which pose some problems of analysis owing to the presence of humic and fulvic material and other interferences; moreover, food and sediment samples also represent a problem in analysis, owing to the interfering matrix or sugar and fat content; and (iii) a highly efficient separation and detection technique is required to determine numerous isomers or congeners and compounds with different polarities and physicochemical properties. For such reasons, it is obligatory to use validated methods since more and more different laboratories need to compare the levels of OPPs in different matrices for QA purposes. To compare results, one has to prove that the method used is accurate and precise and that these parameters hold with time.

To test the performance and validate a method, certified reference materials are used. There are two main types of reference materials. The first type consists of high-purity mixtures of compounds of one chemical class dissolved in a pure organic solvent, and are used for calibration of the analytical system, for identification of the analytes and for spiking the samples, in other words, for method performance. The second type is used to assess the whole analytical procedure, from the extraction of the analytes to the final analysis, which is performed by participating in interlaboratory calibration exercises. The advantage of participating in interlaboratory exercises is that each laboratory can validate a new-sprung extraction and detection method by comparing it with well-known and established techniques, such as GC. Lacorte et al. reported the validation of SPE coupled on-line with LC/DAD, LC/TSPMS and LC/APCIMS for the analysis of OPPs in ground and wastewaters. The established procedure for validating an analytical method includes the evaluation of several quality parameters, such as: (i) linearity of the detector for establishing the minimum and maximum concentrations that can be handled; (ii) DL, measured from the calibration curve and taking a signal-to-noise ratio (S/N) of 3 (it should be verified experimentally); (iii) the limit of quantification (LOQ), which is calculated taking an S/N of 10; (iv) precision or repeatability of the technique, which indicates the percentage error made in consecutive analyses, without changing any experimental conditions; for a standard injection, it should be 1–2%, and for a whole analytical procedure (e.g. analysis of waters) it can rise to 10%, which is the allowed error according to the USEPA; (v) reproducibility, or variation of the analytical response between-day precision, keeping all the experimental conditions equal; under controlled conditions (column oven, mobile phase, pH, etc.), the reproducibility should not be much higher than the repeatability, but in practice, it is seen that many MS detectors do not respond in the same way since the ionization efficiency can vary substantially in different days, and to avoid this problem one should work with internal standards; (vi) recoveries, which should be between 70 and 130% for the tested analytes, according to the USEPA; and (vii) accuracy or determination of the relative difference between the experimental value and the true value, which should be checked in interlaboratory calibration exercises.

To summarize, validation of analytical methods is important not only to prove the accuracy and reliability of an analytical method, but also to be able to compare results obtained in different laboratories. Validation is tedious but needs to be done.

8 CONCLUSIONS

The analysis of OPPs in water and food samples include three main steps: extraction, cleanup and detection. The present trend is the use of multiresidue, automated methods for the surveillance of pesticides and their degradation products in environmental samples. For water samples, LLE, which used to be the most
popular method, has been replaced by SPE, which has the advantage that it is less laborious, quicker, diminishes solvent consumption, can be used as storage media and produces more reproducible results. Both on-line and off-line SPE can be nowadays automated by sophisticated equipment such as the Prospekt, the OSP-2 and the ASPEC or Zymark, respectively. Since manipulation of the water sample is minimized, these techniques produce extremely precise and accurate results. Different types of packing materials for SPE (e.g. silica-based C₈ and C₁₈, styrene–divinylbenzene copolymeric materials, immunosorbents and MIPs) provide an extremely selective way to trap compounds of diverse physicochemical properties. The advent of immunosorbents or MIPs will certainly increase the efficiency of a selective extraction both from water and food samples and will minimize the sample cleanup.

Food samples represent a more complex matrix owing to their great versatility and the presence of fats and sugars. Food samples are freeze-dried and pesticides are extracted by Soxhlet or ultrasonic methods. Sample cleanup using GPC or column chromatography with Florisil, alumina or other sorbents is essential to eliminate matrix impurities. Generally, the analysis of food samples requires a high degree of manipulation and there is a need to optimize the analytical technique for each type of food matrix.

In all cases, sampling, transport and storage of the water or food samples should be carefully performed to avoid sample deterioration or degradation of the pesticides. Normally, samples are transported refrigerated and kept preferably at −20°C.

Most commonly, OPPs are analyzed by GC, which is a well known and established technique for OPP monitoring and is the official method adopted by the USEPA. The high sensitivity of GC methods, together with the high separation efficiency and speed of analysis, favors multidimensional analysis and routine monitoring. GC with NPD and ECD are the most common techniques, and analysis has to be performed with two columns of different polarity or using MS detection. In this way, it is possible to confirm the presence of a pesticide in water or food samples. GC/MS methods are sensitive, selective and reproducible and offer structural information. GC/MS with EI produces abundant fragment ions and the analytes can be identified by library spectral matching whereas NCI gives molecular information and is more sensitive and selective for electronegative pesticides. The main disadvantage of GC is that it cannot handle polar, non-volatile or thermolabile compounds without a previous derivatization step.

In the last few years, new technologies based on HPLC systems have been developed to determine organic pollutants in the environment. UV and DAD are the most common detection devices used for determining priority pesticides in water and food matrices. LC/DAD has the advantage that it gives a UV spectrum that can be used for identification and confirmation purposes. LC can be coupled to MS with different types of interfaces, such as PB, TSP and the recent API techniques. API interfaces have slowly replaced the others since they can produce abundant fragmentation by increasing the electrical field in the intermediate region of the mass analyzer so that CID spectra can be obtained by a single quadrupole. Compared with PB and TSP, API techniques are highly sensitive, with DLs at the picograms level, reproducible and have a linear range over various orders of magnitude. Moreover, provided an efficient preconcentration technique is applied, it is possible to quantify the analytes at the nanograms per liter level, similar to what is obtained with GC. As a consequence, LC/MS is becoming a highly robust technique and the preferred option for the identification and confirmation of OPPs in routine monitoring programs.

With regard to qualitative assurance, all the analytical techniques have to be validated in order to provide reliability of the results. This is important for qualitative control and to allow the comparison of the results provided by different laboratories. The analysis of certified samples is important in order to establish the accuracy of each method and it is necessary before a technique can be implemented in routine monitoring programs concerning OPPs.

**1 INTRODUCTION**

Environmental management depends on information on a wide range of compounds. Unreliable or inaccurate information may lead to large economic losses which are caused, for example, by sanitation measures that are not needed, or to unacceptable risk to the environment or human health if necessary measures are not taken.

Method development within environmental areas is of great importance in helping to obtain the selectivity and sensitivity necessary for monitoring low levels of toxic substances as required by environmental regulations. Analytical techniques that fulfill these requirements can be achieved by the use of chromatographic separation steps coupled with selective sample handling techniques. In these steps, the pesticides are separated from the many matrix substances and simultaneously enriched. Goals are also reached by striving for more selective detection principles and techniques, such as mass spectrometry (MS) combined with GC or HPLC. Immunoassays offer certain advantages over conventional instrumental methods for the analysis of pesticide residues and are ideally suited for screening a large number of samples for low levels of specific analytes.

New groups of pesticides have been invented for plant protection at low doses, with a reversible mode of action, less persistence, systemic action and adequate potency against crop pests. A critical review of the analytical methodology used to determine these newly developed pesticides is required so that the methods of analysis evolved for the generation of data can be used as standards.
2 DESCRIPTION

There are many registered chemicals that can be included under the heading of miscellaneous pesticides and related compounds which comprise a large group of substances with very different characteristics and applications.\(^1\) Their common attribute is that they do not belong to the classical chemical categories of pesticides, such as organochlorines, organophosphates, carbamates or triazines.\(^2\) However, depending on their chemical structure they can be classified into several chemical classes, the most important of which are macrocyclic lactone, chloronicotinyl, tetraneortriterpenoid, ammonium quaternary salt, dinitroaniline, acetamide, oxime, triazole and pyridine-based molecules. Table 1 shows the chemical structures and some examples of the major classes that could be considered to be miscellaneous pesticides.

The avermectins are macrocyclic lactones produced by the soil microorganisms *Streptomyces avermitilis*. Two avermectins have been commercialized to date. The semisynthetic 2,2,2,2,3-dihydroavermectin B\(_1\) known as ivermectin is used as an antiparasitic drug in animals and as defoliants on crops such as cotton and as desiccants for pineapples, potatoes, sugarcane and sunflower. CQ and MQ chloride are cationic plant growth regulators, structurally related to the bipyridylum herbicides, which are mainly used to prevent loging in barley and rye and also to increase the yield of cotton.

Dinitroanilines are selective pre-emergence herbicides used to control some broad-leaved weeds and the major annual grasses in a wide variety of agronomic crops. They disrupt mitosis in the meristematic cell of seedling plants by inhibiting the formation of microtubules.

The group of acetamide pesticides (some also known as chloroaacetamides) encompasses a considerable number of herbicides and fungicides used to control weeds and fungi in crops. The compounds are widely used to control annual grasses and certain broad-leaved weeds in corn, soybeans and peanuts and to control phytopathogenic fungi (*Peronosporales*) in potatoes, sugar beets, and other crops. They act by inhibiting protein synthesis by reaction of the activated Cl atom of the chloroaacetyl group with reactive sites in proteins.

Oximes are bioactive compounds, originally discovered in insects, that have recently been synthetized, and some are effective herbicides.\(^5\)

Triazole derivatives are aromatic heterocycles widely used as weed killers, fungicides, insecticides, plant growth regulators and antimicrobial agents.\(^6\) They are nonselective systemic herbicides used against a wide variety of plants.

Pyridine-based molecules are a group of substances that include pyridazines, pyridazones and pyridones. All of them are herbicides but their applications vary. For example, Pyridate is a pyridazine that acts by contact while pyridazine derivatives such as norflurazon and cloridazon are soil-applied herbicides and fluridone, a pyridone, is an experimental herbicide developed for aquatic plant management systems.

3 CHARACTERISTICS

3.1 Physical and Chemical Properties

In order to develop the best residue analytical methods with the most appropriate instruments, a knowledge of the physical and chemical properties of the pesticides is essential. For example, it is impossible to develop a GC residue method for imidacloprid without derivatization because of the very polar and nonvolatile properties displayed by this molecule. Similarly, a direct GC method for DQ, PQ or azadirachtin is also impossible because of the polarity of these compounds. The physical and chemical properties of some typical herbicides are shown in Table 2.

The avermectins are a family of macrocyclic lactones. Abamectin is a mixture of two components. The major one is avermectin B₁₉, which makes up 80% or more of the mixture, and the minor component is avermectin B₁₇, which supplies 20% or less; the two components differ in a single methylene group. Ultraviolet (UV) light below 280 nm rapidly isomerizes the E (trans) 8,9 and 10,11 double bonds of avermectin to 8,9- and 10,11-Z isomers. However, solutions of avermectin in Pyrex flasks are generally stable because Pyrex excludes most of the UV light below 280 nm. Avermectin residues degrade rapidly by both oxidative and photochemical pathways, forming a variety of products when applied to a number of different crops. Therefore, the only residues of toxicological significance are avermectin and 8,9-Z avermectin.

Ivermectin is synthesized from avermectin by reducing the 22,23-double bond, thus producing dihydroavermectin B₁₉ and dihydroavermectin B₁₇. These compounds are notable for their potent anthelmintic and insecticidal activities.

Emamectin benzoate (MK-224, MAB₁ benzoate, 4-deoxy-4-epimethylamino avermectin B₁) is a derivative of abamectin and consists of two avermectin homologs, each with a molecular weight of approximately 900. By specification it consists of at least 90% 4'-deoxy-4'-epimethylaminoavermectin B₁₉ benzoate and not more than 10% of 4'-deoxy-4' epimethylaminoavermectin B₁₇ benzoate. These components differ only in a methylene group on the C-25 side chain. Emamectin benzoate is an effective insecticide against lepidopteran larvae and is currently under development for use on a number of crops including celery, lettuce, cabbage and tomato.

Emamectin benzoate is an ionizable salt and displays higher water solubility than other avermectins but binds very tightly to topsoil and is, therefore, immobile.

Soil biodegradation studies on the chloronicotinyl imidacloprid have demonstrated that its major metabolite is 6-chloronicotinic acid, and that it leaves no soil residue after the first 3 months. Acetamiprid is stable in solution at pH between 4.5 and 7. It is slowly degraded at pH 9 and 45 °C.

Azadirachtin is nonvolatile and highly polar. It has UV absorption due to the α,β-unsaturated carbonyl chromophore in the ligate ester and the vinyl ether, but the absorption maximum is at a very short wavelength. Azadirachtin hydrolyzes readily at 35 °C, and its disappearance follows simple pseudo-first-order kinetics. Its hydrolysis is faster at a basic than an acidic pH.

DQ is marketed as a dibromide and dibromide monohydrate salts and as a base. PQ is marketed as a chloride and dimethyl sulfate salts and DF is marketed as methyl sulfate salts. The PQ salts are hygroscopic, not volatile and very soluble in water. PQ is extremely stable in the presence of acids but it is destroyed quickly in a basic medium. It is soluble in water and insoluble in organic solvents. DQ is also very thermostable and not volatile. The herbicide activity of PQ and DQ is related to the planar structure of their molecules and the 18 possible resonant structures that stabilize the radical formed in reduction reactions in which they are involved. DF salts are very soluble in water and are stable to hydrolysis. DF is stable at weakly acid pH but is degraded in strong acids and in the presence of oxidizers. The three herbicides present an absorption band in the UV at 260, 310 and 255 nm, respectively, due to the presence of aromatic rings in their structures.

Although the dinitroaniline herbicides are chemically related, they differ in volatility, persistence in soil and absorption by crops, and for this reason may differ in their effects on soil, plants and air. These compounds are among the least mobile herbicides, and therefore runoff is the principal route of the contamination of surface waters. Dinitroaniline herbicides are water insoluble, relatively volatile and strongly adsorbed to soil colloids. In soil, both chemical reactions and biological processes degrade pendimethalin. In general, dinitroaniline herbicide degradation is more rapid under flooded anaerobic conditions than under aerobic ones.

Acetamide herbicides have moderate water solubility and are rapidly absorbed into plants. In susceptible plants, the herbicides act by inhibiting protein synthesis, whereas insensitive plants rapidly inactivate these herbicides via glutathion conjugation. In sensitive fungi, the structurally related fungicides have effects on RNA synthesis. As these reactions involve various chiral structures, some stereoselectivity is expected in the activity of these compounds.

Oximes are bioactive compounds originally discovered in insects. Field trials with these compounds showed that they were not consistently effective, perhaps because of the instability of this active ingredient. Sethoxydim undergoes degradation, including photodegradation. Clethodim is also degraded in aqueous solution by acid medium and light. Clethodim degradation increases as solution pH decreases and photolysis is more rapid and more complete than hydrolysis.

Amitrole belongs to the triazole group and is soluble in water, methanol, ethanol and chloroform, slightly soluble in ethyl acetate and insoluble in ether and acetone. Aqueous solutions are neutral.

Pyridate is a colorless crystalline solid that melts at 27 °C and boils at 220 °C under 10⁻⁶ mbar vacuum. Its vapor pressure is 1.3 × 10⁻⁹ mbar at 20 °C. It is stable in neutral medium, but is hydrolyzed in strong acid and strong alkali media.
3.2 Toxicology

Pesticide residues are regulated at the international and national level according to the toxicity of the pesticide and the human exposure to a particular substance. Table 3 lists the acute oral and dermal toxicity for different animal species, chronic toxicity for dogs, and the ADI.

The macrocyclic lactones are neurotoxins that manifest their action by disrupting the normal function of γ-aminobutyric acid (GABA), an important neurotransmitter in the central nervous system of vertebrates and in the peripheral nervous system of invertebrates. Because mammals only have GABA ergic synapses in the central nervous system, the mammalian blood–brain barrier ensures a degree of specificity. A notable feature of this group of compounds is their low LD50 (lethal dose 50) values, but they are not usually highly toxic by the dermal route on account of their large molecules and poor transdermal absorption. In vitro studies with preparations of rat brain have shown that avermectin B1a stimulates presynaptic binding of GABA and enhances postsynaptic binding of GABA; the action of avermectin B1a is antagonized by bicuculline and picrotoxin. (21)

Avermectin and ivermectin are metabolized in a qualitatively similar way among different species. The major metabolites of both in cattle, sheep, swine and rats are either 24-hydroxymethyl or 3\(^{-\text{O}}\)-desmethyl derivatives. However, the enzymes responsible for the metabolism have not been identified in any species. (7)

These compounds undergo little metabolism and most of the dose given to the animal is excreted relatively unaltered, primarily in the feces. (3) Abamectin induces teratogenic effects such as cleft palate.

The chloronicotinyl insecticides interfere with neuronal functions as do organophosphate, carbamate and pyrethroid insecticides. Unlike the latter pesticides, they act on nicotinic acetylcholine receptors on the

NOEL, no observable effect level; ADI, admissible daily intake.
PQ toxicity in both experimental animals and humans targets primarily the lung, whereas DQ does not. It is believed that the differences between PQ and DQ are a result of the fact that the lung selectively accumulates PQ and not DQ. PQ-induced pulmonary injury takes place in two phases: destructive and proliferative. It has been suggested that the biochemical reactions that lead to the destructive effect of PQ are analogous to its toxic action on plant cells. NADPH (nicotinamide adenine dinucleotide phosphate (reduced form)) is the donor for the single-electron reduction of PQ. Reduced PQ is reoxidized rapidly by molecular oxygen and superoxide radicals are formed. The superoxide radicals initiate a chain of reactions that produce toxic reactive intermediates that include hydrogen peroxide and hydroxy radicals and also produce lipid peroxidation. They are responsible for the disruption of cellular membranes. In addition, PQ competes for and deprives other systems of essential NADPH and compromises their cellular integrity.\(^{23,24}\)

DQ poisoning differs from that of PQ in that the renal effects are more prominent and lung changes do not generally occur. An effect of DQ that has been extensively investigated is its ability to produce cataracts in experimental animals.\(^{23}\) PQ produces chronic effects such as costal cartilage malformation in rats when injected during the gestation. It appears that the teratogenicity of PQ results from its effect on collagen biosynthesis.\(^{24}\)

CQ is known to be a competitive inhibitor of cholinesterase in animals. This anticholinesterase chemical causes acetylcholine accumulation at cholinergic receptor sites and thus is capable of producing effects equivalent to excessive stimulation of cholinergic receptors through the central and peripheral nervous system.\(^{25}\)

Substituted anilines have the general property of causing methemoglobinemia, as do many other aniline derivatives. The probable mechanism of methemoglobinemia is N-hydroxylation to the corresponding hydroxylamine, which then takes part in an intraerythrocytic cycle with the corresponding nitroso derivative generating methemoglobin at the same time. Alachlor is classed as a probable human carcinogen by the USEPA (United States Environmental Protection Agency)\(^{26}\) because of its carcinogenic effect on rodents, where it produces posterior nasal and stomach tumors, possibly by a nongenotoxic mechanism.

Little is known of the human metabolism of amitrole but experiments with \(^{14}\)C-amitrole orally administered to rats show that 80–90% of the compound is excreted unchanged in the urine.\(^{27}\) The International Association for Research on Cancer (IARC) classifies amitrole as a possible human carcinogen that produces thyroid tumors apparently through an indirect mechanism. Amitrole inhibits thyroid peroxidase, thus lowering the thyroxin level. The thyroid gland becomes hyperplasmic and eventually forms tumors.

The literature is scarce on toxicity of the oximes. There are only a few studies demonstrating that sethoxydim produces lesions in bone marrow and the liver of dogs.\(^{28}\)

In laboratory metabolism studies with \(^{14}\)C-fluridone, a major fluridone metabolite, 1-methyl-3-(4-hydroxyphenyl)-5-[3-(trifluoromethyl)phenyl]-4-(1H)-pyridine was present in bluegill and fathead minnows at levels equivalent to 50% and 15% of the total residue in fish, respectively.

### 3.3 Regulations

A legal tolerance is defined as the maximum level or concentration of a pesticide, or its metabolites or derivatives, that is permitted in or on a particular food crop or food product. The amount is generally no higher than the concentration present in or on a particular food crop or food product as a result of good agricultural practices.

The European Union (EU) has proposed rigid limits for pesticides in drinking water, especially 0.1 μg L\(^{-1}\) (0.1 ppb) for a single pesticide and 0.5 μg L\(^{-1}\) (0.5 ppb) for total pesticides including their degradation products.\(^{29}\) In the United States, USEPA has set values for maximum contaminant levels for pesticides individually. The USEPA values range approximately from 1 μg L\(^{-1}\) to 1 mg L\(^{-1}\) (1 ppb to 1 ppm).\(^{30,31}\) Such levels are more specific than EU levels, which are fixed for all the individual pesticides without making any distinction between individual pesticides of different toxicity.\(^{32}\) However, of all the pesticides covered in this article, USEPA has only established a health advisory level of 20 μg L\(^{-1}\) for DQ.\(^{31}\)

The maximum levels of these miscellaneous pesticides in fruit and vegetables allowed in the EU are shown in Table 4.\(^{33–36}\) Maximum levels in animal tissues, other biological samples or different environmental compartments have not been established. These established tolerances are revised periodically and the tendency is to diminish the permitted levels. This fact poses substantial analytical problems and demands a methodology of greater sensitivity.

### 4 ISOLATION OF THE SAMPLE

#### 4.1 Macrocyclic Lactones

Abamectin has been determined in ambient air and on surfaces following their treatment with the pesticide. Surface sampling was performed with cotton dosimeters.
with or without wetting solutions such as 2-propanol. Air sampling is achieved in Teflon™ filters or in Orbon™ 42 tubes. Teflon™ air filters and cotton dosimeters were extracted with acetonitrile using amber jars or Soxhlet™. Cleanup was done by diluting with the ionized water passing through octyl (bonded C₈) and amipropyl (-NH₂) solid-phase extraction (SPE) columns. (37,38)

Emamectin benzoate was concentrated from water on C₈ SPE cartridges and eluted with acetate ammonium in methanol. (10) The methods described for the determination of macrocyclic lactones from vegetables require complicated homogenization/extraction schemes. Fruit and vegetables are mainly extracted with acetonitrile/water/hexane (1:1:5). Abamectine and its δ 8,9-isomer are concentrated by passing the hexane layer through an aminopropyl SPE cartridge. (39–43) Lettuce and cucumber are extracted with ethyl acetate and the extract is purified by SPE using a Sep-Pack™ silica cartridge. (44) Emamectin benzoate is extracted from lettuce and celery with methanol, and the extract is cleaned up on a C₈ cartridge followed by LLE (liquid–liquid extraction) with ethyl acetate before passing through a propyl sulfonyl cation-exchange cartridge. (45)

Abamectin residues from soil samples have been extracted with acetonitrile. (9,21) The insecticide abamectin is extracted from soil and animal tissues using supercritical-fluid extraction (SFE). (46) Supercritical carbon dioxide

MRL, maximum residue limit; CM-1, methyl 5-(l-aminobutylidene)-2,2-dimethyl-4,6-dioxocyclohexanecarboxylate.

modified with 9% 2-methoxyethanol extracts abamectin from soil samples without the need for cleanup. Abamectin is also easily extracted from animal tissues without interfering coextractives.

Fish tissues have been extracted with acetone/methylene chloride and cleaned up with aminopropyl cartridges. A simple specific procedure for determining avermectin B₁ in biological samples has been described and is based on the development of a specific antiavermectin B₁ immunosorbent. Avermectin B₁ is extracted from cattle plasma, cattle meat and pear samples. The extracts are cleaned up on a SPE column (C₁₈) and an immunoaffinity column. Recoveries of avermectin B₁ from samples spiked at levels of 6 and 60 ppb ranged from 80–86%, with coefficients of variation of 5–14%. Feces samples are extracted with an acetone–water mixture, partitioned with isooctane and cleaned up with a C₁₈ cartridge.

4.2 Chloronicotinyls

To quantify imidacloprid in liquid and solid formulations samples were extracted in solvent or dissolved in acetonitrile. Water samples were extracted with C₁₈ SPE. For extraction in vegetables, the acetone–dichloromethane extraction followed by a cleanup step on a C₁₈ cartridge system is selected owing to the good recovery values. Rice and cucumber are extracted with acetonitrile–water (80:20) and silica gel
column chromatography.\(^4\) Soil samples are shaken with acetonitrile–water,\(^\text{4,5,1}\) acetonitrile–methanol–water\(^\text{11}\) or with chloroform.\(^\text{53}\)

Acetamiprid in crops has been extracted with methanol, cleaned up by liquid–liquid partition with \(n\)-hexane or dichloromethane, and Florisil\(^\text{TM}\) column chromatography used to remove interferences.\(^\text{54,55}\)

### 4.3 Tetranortriterpenoids

Azadirachtin has only been determined in insecticidal formulations of kernel extract. Neem seed powder has been extracted by chloroform in a percolator\(^\text{96}\) or by hexane in a Soxhlet\(^\text{57}\). Insecticide formulations were dissolved in methanol–water (90:10) and C\(_\text{18}\) SPE was used to retain unwanted material.\(^\text{52}\) SFC has also proven to be a suitable system for determining azadirachtin in crude extracts of neem.\(^\text{12,58}\)

### 4.4 Ammonium Quaternary Salts

Water samples containing more than 1 \(\mu\text{g mL}^{-1}\) can be analyzed directly.\(^\text{14,59,60}\) The determination of trace amounts of DQ, PQ and DF in natural and drinking waters requires a preconcentration step before the HPLC determination. SPE techniques are frequently used with C\(_\text{18}\),\(^\text{61}\) C\(_\text{8}\),\(^\text{62}\) silica,\(^\text{17,63–65}\) graphitized carbon black (GCB)\(^\text{66}\) and ion-exchange column chromatography.\(^\text{59,67,68}\) Water sample treatment by isotachophoresis\(^\text{69}\), electrodialysis\(^\text{70}\) and flow-injection analysis (FIA)\(^\text{71–73}\) has also been reported.

Traditional methods of determination in fruit and vegetable crops include matrix maceration with acid solution and isolation with silica columns\(^\text{16,74–77}\) or cation exchange resin.\(^\text{78}\) DQ and PQ can also be isolated after derivatization and LLE with diethyl ether.\(^\text{79}\) The separation of MQ after acid maceration can be carried out by partition with hexane followed by a cation exchange column.\(^\text{80}\) DQ and PQ can be analyzed in edible oil after sonication with a phosphate buffer and cleanup with C\(_\text{18}\) cartridges.\(^\text{81}\) CQ has been extracted from crops by maceration with methanol and after concentration, partitioned with hexane prior to alumina cleanup.\(^\text{82}\)

Methods of determination in soil are similar to those reported for fruit and vegetables and involve matrix maceration with acid solution and isolation with cation exchange resin\(^\text{78}\) or by partitioning with dichloromethane.\(^\text{15}\)

Several methods are available for measuring DQ and PQ in biological fluids. DQ determination in blood serum and urine is performed directly after precipitating the proteins and filtration,\(^\text{78,83–85}\) DQ and PQ have been extracted using ion-pair extraction into organic solvents\(^\text{86–90}\) and ion-pair SPE, using disposable cartridges of C\(_\text{18}\).\(^\text{91}\) The latter method is rapid, easy to perform and provides high recovery values. Cianopropyl extraction columns\(^\text{92}\) or silica columns\(^\text{93}\) have been applied to determine DQ and PQ in human samples (blood, urine, milk) by direct SPE. Simultaneous determination of PQ and DQ in tissues is achieved after homogenization with perchloric acid.\(^\text{94}\) If further cleanup is required, the mixture is centrifuged and after adjusting the pH of the supernatant is passed through C\(_\text{18}\) cartridges.\(^\text{95,56}\)

### 4.5 Dinitroanilines

Formulations containing benfim and trifluralin have been extracted in hexane.\(^\text{97}\) Dinitroaniline herbicide concentrations in soil and plants have usually been measured after sample extraction with an organic solvent and purification using Florisil\(^\text{TM}\) cartridges\(^\text{98}\) or glass chromatography columns packed with Florisil\(^\text{TM}\).\(^\text{99,100}\)

A method based on the extraction of soil samples in small columns has been used to determine dinitroanilines. Acetone/water (90:10) was used for the extraction of simazine. Pendimethalin is extracted from soil with an extraction solution containing acetonitrile, water and glacial acetic acid and partitioning with \(n\)-hexane.\(^\text{101}\)

Simultaneous determination of the dinitroaniline herbicides dinitramine, ethalfluralin, trifluralin, pendimethalin and isopropalin in soil and surface water has been reported.\(^\text{10}\) The soil was extracted with diethyl ether and analyzed without any cleanup. The water was analyzed after purification and concentration on C\(_\text{18}\) cartridges.

### 4.6 Acetamides

Acetamide herbicides have been isolated from river water and rain samples by SPE with C\(_\text{18}\)\(^\text{102–111}\) styrene–divinyl benzene copolymer.\(^\text{112}\) XAD-2 resin\(^\text{113}\) carbon black\(^\text{114}\) or by LLE with dichloromethane\(^\text{115–117}\) or hexane.\(^\text{26}\)

Acetamides in crops have been determined after extraction of metabolites obtained by hydrolysis. The anilines were isolated by steam distillation and partitioned with Superclean\(^\text{TM}\) ENV-Chrom P.\(^\text{118–120}\) Soil was extracted with ethyl acetate\(^\text{120}\) or with methanol–water (9:1) followed by SPE with C\(_\text{18}\).\(^\text{111}\) SFE was applied for the detection of herbicides in meat samples\(^\text{121}\) and soil samples.\(^\text{122,123}\)

### 4.7 Oximes

Few analytical methods have been reported for extracting and concentrating oxime herbicides from different matrices. An analytical method for the total content of allosydim-sodium herbicide and its degradation products
in groundwater has been developed based on concentration by evaporation of water and ethyl acetate partitioning after derivatization of the analytes with H₂O₂. Residue analysis of the herbicide sethoxydim and its major active metabolite was also performed in rapeseed. The extraction procedure was based on celite–methanol extraction, which requires complicated partitioning mainly with CHCl₃. Recoveries ranged from 83 to 102%.

### 4.8 Triazoles

Commercial samples of amitrole have been analyzed. The samples used were “Compo-Total-Unkrautvernichter” from Compo GmbH (composition: 10% amitrole, 25% simazine, 25% diuron) and “Domatol Spezial” (composition: 38% amitrole, 16% MCPA (4-chloro-2-methylphenoxacyetic acid), 19.5% simazine) obtained from a plant protection office in Trier, Germany. The determination can be performed directly with solutions of the commercial herbicide formulations.

The difficulty of determining aminotriazole at trace levels in water is linked to the necessary extraction and concentration from the aqueous media. LLE or SPE cannot be performed with the classical sorbents owing to the low solubility of aminotriazole in organic solvents and its high solubility in water. Since aminotriazole is ionized at a low pH, an ion exchanger can be used to extract it from water. However, the effect of the inorganic cations causes rapid breakthrough in drinking water. It is also possible to use an ion-pairing preconcentration. The most reported method for concentrating this compound is evaporation of water.

In spite of all the above, a fast method for the determination of amitrole in drinking and groundwater has been reported. Amitrole is separated from other substances by HPLC with a coulometric electrode array detector. Tap and well water with concentrations down to 0.1 μg amitrole L⁻¹ can be determined without any enrichment step using this method. An HPLC method for direct determination of amitrole in urine has also been described based on derivative formation.

Determination of amitrole in tissues has been performed after extraction of the material with methanol. The cleanup procedure includes chromatography on aluminum oxide and gel permeation chromatography to eliminate hydrophilic substances. The average recovery is 80%.

Amitrole has been extracted from plant tissues and sandy soils with ethanol, adsorbed on a resin and desorbed with ammonia. After acetylation with acetic anhydride and cleanup over a Sep-Pack silica cartridge, the amitrole-acetyl derivative is determined by GC. The average recoveries are between 81 and 96%.

### 4.9 Pyridine-based Molecules

A study comparing two SPE extraction methods for the analysis of thiazopyr and its monoacid metabolite in groundwater has been reported. One of the methods is based on SPE with C₁₈ extraction disks and the other with GCB. Recovery studies indicate excellent recovery percentages for thiazopyr and thiazopyr monoacid by both methods.

Thiazopyr residues have also been determined in soil, grass weed and seedlings of woody plants by GC. The herbicide was extracted from soil and plant samples with ethyl acetate and plant extracts were cleaned up on a Florisil column. The average recoveries were always higher than 97% with a relative standard deviation between 1 and 6%.

A method has been presented for determining the aquatic herbicide fluridone. Samples are passed through a Sep-Pack C₁₈ cartridge to extract fluridone and eluted with methanol. Recoveries averaged 98%.

Residue methods for determination of fluridone in meat, milk, eggs, crops, fish and crayfish have also been described. Fluridone is extracted from meat, eggs, crops, fish or crayfish with methanol, and the herbicide is extracted from milk with a disposable C₁₈ cartridge. Extracts are purified by liquid partitioning and/or alumina column chromatography. When the metabolite of fluridone is determined together with the parent compounds, the methanolic extracts are subjected to acidic hydrolysis to release the conjugated forms of fluridone and the metabolite.

Norflurazon and its initial metabolite in soil have been determined. The method consists of soil sample extraction with methanol. Recoveries from fortified soils were >90% for norflurazon and >80% for desmethylnorflurazon.

The conditions for recovering the herbicide chloridazon from the soil were studied using acetone as the extractant reagent, and the optimum conditions were a time of 15 min for a single extraction. Results showed that 85.7% of the chloridazon was recovered from soil samples.

A metabolite of the herbicide pyridate (3-phenyl-4-hydroxy-6-chloropyridazine, known as CL9673) has been determined in drinking and groundwater. A recovery study using tap water samples spiked with CL9673 at a concentration of 0.1 μg L⁻¹ showed a recovery of 84.8%.

Pyridate and its metabolite have also been determined in green cereals, grain and straw. Samples were macerated with acetone–celite and filtered. The acetone extracts were evaporated. The aqueous residue was transferred to a separating funnel with sodium acetate and dichloromethane. The dichloromethane phase contains the herbicide pyridate, and the sodium acetate phase contains the metabolite. Each phase was then extracted further. In the 0.05–1.0 mg kg⁻¹ range, recoveries are
between 73.7 and 109% from green plants, between 77 and 102% from grains and between 77.3 and 87.5% from straw.

5 IDENTIFICATION AND DETERMINATION

The wide range of physicochemical properties covered by these compounds explains why many analytical techniques have been used to determine them. Table 5 summarizes the techniques employed for the compounds’ determination. As can be observed in the table, HPLC is the procedure most employed to separate and detect miscellaneous pesticides. This may be attributed to general guidelines that have been established to generate new pesticides, less hazardous for human beings. Pesticides are being made more water soluble, more polar and less volatile. This group of characteristics makes HPLC an ideal technique for determining them.

5.1 Gas Chromatography

Direct determination of imidacloprid by GC is not possible because of its thermolabile and polar N-nitroguanidyl moiety. However, a method for determining imidacloprid in water and soil samples, after hydrolysis in a basic medium, followed by chromatography–MS and selected ion monitoring (SIM) has been reported.\(^{(53)}\)

In contrast, acetamiprid is directly determined by GC with electron-capture detection (ECD).\(^{(54)}\) The operating conditions of GC include the use of a packed column. The inlet and detector temperatures were both 320 °C, and the column temperature was 260 °C. In the same context a method for determining acetamiprid and its metabolites was developed by GC/ECD. Acetamiprid and its metabolites in crops were derivatized to methyl 6-chloronicotinate through alkali hydrolysis, potassium permanganate oxidation and then esterification with diazomethane.\(^{(55)}\)

Bipyridylium herbicides cannot be determined by GC unless they are converted into volatile compounds. Reduction of DQ and PQ with NaBH\(_4\) in the presence of a catalyst such as NiCl\(_2\) makes it possible to obtain the hydrogenated derivatives that could be detected by a NPD (nitrogen phosphorus detector).\(^{(79,84)}\)

CQ is also determined by GC.\(^{(82)}\) The technique is based on an in vitro multistep reaction by which CQ is initially N-demethylated with a potassium pentafluorothiophenolate followed by a further reaction with an excess of reagent to produce the pentafluorothiophenyl derivative. ECD and MS were used for quantitative determination and identification. However, Mortimer and Weber\(^{(192)}\) reported that the method contains a significant error and it is not specific for CQ.

Determination of dinitroaniline herbicide concentrations in soil, air and plants has usually been carried out by GC with ECD,\(^{(98,101)}\) NPD\(^{(99,153–155)}\) or MS.\(^{(98,99,153,155)}\) The concentrations of these herbicides were determined by both NPD and ECD and confirmed by their mass spectra. In this way, benifin, butralin, dinitramine, ethalfluralin, isopropalin, pendimethalin and trifluralin have been determined, often together with herbicides of other types in several matrices. Figure 1 shows the GC/MS chromatogram at the detection limit of 0.01 µg g\(^{-1}\) of pendimethalin and three other herbicides in soil samples.

However, oryzalin requires a general derivatization method, since the intact chemical does not possess good gas chromatographic properties. The di-N-methyl derivative has been well recognized and conversion of oryzalin to this derivative has been used in determination and characterization by GC/MS.\(^{(157)}\)

Analysis of chloroacetamides has also usually been carried out by GC with different detectors.\(^{(26, 103, 105–108, 110–114, 116, 117, 119, 120, 158–161, 163, 164, 183, 184, 189)}\) With nonspecific detection such as FID (flame ionization detection) the sensitivity of the determination is relatively low and laborious purification of the samples is needed.\(^{(159, 183, 184, 189)}\) To avoid these drawbacks, a comprehensive two-dimensional gas chromatograph with FID was constructed and evaluated for fast separation and analysis of different pesticides, among them alachlor, metalachlor and trifluralin.\(^{(160)}\)

GC/NPD has been applied to the analysis of alachlor, propachlor, butalachlor, metolachlor and two alachlor degradation product residues.\(^{(26, 106, 116, 120, 158)}\) ECD is a highly sensitive detector for these compounds. It has been used in the analysis of acetochlor, alachlor, butachlor, metolachlor and propachlor.\(^{(110, 113, 154, 161)}\) Other authors have used ECD to analyze alachlor and its metabolite after derivatization to the heptafluorobutyryl derivative.\(^{(119)}\) This method is highly sensitive but the analysis is complicated. The detection of chloroacetamides also has been performed using ECD and NPD in parallel.\(^{(105)}\)

GC/MS has been used as a confirmatory technique.\(^{(26, 108, 110, 116, 120)}\) GC/MS also allows routine determination of chloroacetamides simultaneously with other herbicides such as triazines, carbamates and phenoxyacetic acids.\(^{(103, 107, 112, 114, 117, 163)}\) Isotope dilution GC/MS has been used to determine alachlor, metolachlor, atrazine and simazine in water and soil.\(^{(111)}\) Known amounts of \(^{15}\)N, \(^{14}\)C-alachlor and \(^{2}\)H\(_{5}\)-atrazine are added to each sample as internal standards. The GC/MS system with data acquisition in SIM mode was used to quantify herbicides in the extract.

The chromatographic separation of enantiomers and diastereoisomers of some acetamide pesticides was investigated using achiral and chiral GC/MS.\(^{(164)}\) The

CD, conductivity detection. See text for explanation of other acronyms.
compounds studied were alachlor, acetochlor, metalaxyl, metolachlor, and dimethenamid. Whereas alachlor is achiral, all the other compounds are axial- and/or C-chiral and consist of two or four stereoisomers, as is shown in Figure 2.

Alloxydim-sodium herbicide and its degradation product have been determined by GC/MS. Residues were derivatized and transformed into 2-methoxycarbonyl-3,3-dimethylpentane-1,5-dioic acid, which was then determined.\(^{(124)}\)

A GC method with NPD is described for the determination of amitrole in water, plant and soil samples. The method is based on the acetylation of amitrole with acetic anhydride.\(^{(130,133)}\)

Pyridine-based molecules have seldom been determined by GC. Thiazopyr has been the one most often determined by GC and different detectors, such as

**Figure 1** GC/MS detection limit of simazine (Sim), thiazopyr (Th), pendimethalin (Pen) and hexazinone (Hex) in soil samples in SIM (0.01 \(\mu\)g g\(^{-1}\)). (Reproduced with permission from R.A. Pérez, C. Sánchez-Brunete, E. Miguel, J.L. Tadeo, J. Agric. Food Chem., 46, 1864–1869. Copyright (1998) American Chemical Society.)

Note the elution of single peaks from the achiral column. Note the marginal resolution of acetochlor into the atropisomers on the chiral column. Note the resolution of metalaxyl, metolachlor and dimethenamid into two or three isomers on the chiral HRGC column. Abbreviations: AL, alachlor; AC, acetochlor; MX, metalaxyl; ME, metolachlor; DM, dimethenamid. Retention times in minutes. (Reproduced with permission from H.R. Buser, M.D. Müller, Environ. Sci. Technol., 29, 2023–2030. Copyright (1995) American Chemical Society.)
ECD,\textsuperscript{134} NPD and MS\textsuperscript{135,153} have been used. The derivatization of fluridone with phosphorus tribromide to determine it by GC/ECD has been proposed as an alternative or confirmatory procedure.\textsuperscript{137}

5.2 High-performance Liquid Chromatography

Several liquid chromatographic methods have been reported for determining macrocyclic lactone residues in various matrices. HPLC-fluorescence detection after dehydration of the residues with trifluoroacetic anhydride\textsuperscript{10,37–43,45,46,49} is the most widely applied determination technique. The major advantages of this method are instantaneous fluorescence derivatization, high sensitivity, improved selectivity and the ability to quantify ivermectin, avermectin B\textsubscript{1}, emamectin and their 8,9-δ degradation product. Figure 3 shows a typical chromatogram for the derivatized avermectin B\textsubscript{1} containing a B\textsubscript{1a} : B\textsubscript{1b} ratio of about 93 : 7 in untreated whole apples fortified with avermectin B\textsubscript{1} at the 2.1 ppb level.

A more rapid HPLC method has been described\textsuperscript{44} for the detection of abamectin in cucumber and lettuce. The method employs UV detection based on the conjugated-diene chromophore of abamectin, which has an absorbance maximum at 245 nm. This method, however, lacks sensitivity and the δ 8,9-isomer is not measured. In addition, when the method is employed with other samples, it shows matrix peaks that interfere with it and prevent quantification of abamectin. Junsuo and Qian\textsuperscript{148} use immunoaffinity chromatography for clean-up and concentration followed by UV detection.

Several methods have been described for the determination of abamectin and emamectin benzoate using radiolabeled compounds (\textsuperscript{3}H and \textsuperscript{14}C) in a variety of samples.\textsuperscript{9,21,47,141} The samples were analyzed by HPLC and the compounds determined on a direct liquid scintillation counter (LSC).

The chloronicotinyl insecticide imidacloprid has been extensively determined by reversed-phase high-performance liquid chromatography (RP-HPLC) with UV detection at 270 nm using a mobile phase of acetonitrile–water.\textsuperscript{4,50,51} The limits of detection ranged from 0.01 to 1.0 mg kg\textsuperscript{-1} depending on the material analyzed. The methodology for determining imidacloprid residues in vegetables\textsuperscript{52,193} by HPLC diode array detection (DAD) has been developed owing to its suitability for selecting the optimum wavelength for maximum sensitivity and confirmation from UV spectral information.

HPLC with pulse amperometric detection (PAD) has been used to determine the insecticide imidacloprid and its major metabolite 6-chloronicotinic acid in soil. Electrochemical study of the compounds demonstrates the reduction and adsorption processes on the mercury electrodes. PAD overcomes electrode fouling problems by repeated and continuously applying cleaning potentials to the working electrode. The measurement potential was \(-1300\) mV.\textsuperscript{111} Figure 4 gives the chromatograms obtained with amperometric detection in direct current (DC) mode and pulse mode.

Azadirachtin is nonvolatile and highly polar. It is unsuitable therefore for GC and only has UV absorption at a very short wavelength. RP-HPLC has been successfully used for separation and quantification of azadirachtin.\textsuperscript{133,22,56–58} The problem is that common aliphatic and aromatic solvents and surfactants used to formulate the products interfere in the region of the azadirachtin-A peak.\textsuperscript{57}

HPLC is the analytical instrument of choice for ammonium quaternary salts because they are readily soluble in water and in another polar solvent and are not volatile. The most commonly used stationary phases are reversed-phases (RP), comprising silica bonded to carbonate chains of several lengths, mainly C\textsubscript{8} and C\textsubscript{18}. Ion-pair formation in LC (liquid chromatography) with a UV detector is a common technique for determining quaternary ammonium compounds, for example by using hexanesulfonate,\textsuperscript{70} heptanesulfonate,\textsuperscript{60,95} octanesulfonate,\textsuperscript{17,83,89,94} ammonium formate,\textsuperscript{152} ammonium acetate\textsuperscript{67,145} or potassium bromide\textsuperscript{66} as counter ions.

C\textsubscript{18}- and C\textsubscript{8}-bonded silica stationary phases always have free silanol groups that complicate the analysis of quaternary amines like bipyridylum herbicides, provoking the
appearance of tailing peaks and increasing their width, and originating a variation in the retention times even when the same column is used. To avoid this one of four actions can be taken:

1. Choose another type of column.
2. Reduce the ionization of the silanol groups by employing mobile phases of pH < 4.
3. Add a silanol group blocking agent to the mobile phase.
4. Increment the ionic strength of the mobile phase.

In addition to the counter ion, the mobile phases reported contain an acid, such as phosphoric acid\(^{15,17,61,62,70,81,89,94-96,152,194}\) glacial acetic acid\(^{67}\) or trifluoroacetic acid\(^{145}\) together with a silanol group blocking agent, such as diethylamine\(^{17,70,89,94,154}\) or triethylamine.\(^{95,96}\) Because of the basic character of the latter, they also help to maintain the pH around 3.

In order to avoid the free silanol group effect, analytical columns are being substituted for the base made from silica particles for polymeric packings such as polystyrene–divinylbenzene. These columns are also more resistant to the acid pHs.\(^{16,68}\) The mobile phases contain phosphoric acid and triethylamine.

The utility of silica as a stationary phase for HPLC analysis of quaternary ammonium compounds has been discussed.\(^{63,64,76,77}\) A silica column with sodium chloride as an ion-pair reagent in acetonitrile–water as the mobile phase provided rapid efficient selective separation of PQ and DQ.\(^{76,77}\) The mechanism involved in this chromatographic process has not been well defined and the interactions between the normal phase (NP) and the herbicides may include ionic interactions between the positive charge of the ammonium quaternary group and the negative one of the silanol group. The herbicide fixed to the silica can be liberated using displacing agents in the mobile phase such as tetramethyl ammonium.
An aqueous mobile phase with sulfonate-type counter ion-pairing extraction system was used. The elution was performed with a gradient of pH 3 aqueous solution of tetramethylammonium hydroxide and ammonium sulfate, and methanol. A hypercarb column was found to give a low probability of false positives for bipyrindylidrine herbicides because it is selective for polar compounds.

Conventional detection of ammonium quaternary compounds in HPLC is usually achieved with UV and DAD detectors. The most commonly used is the UV detector, monitoring wavelengths of 310 nm for DQ, 255 nm for PQ and 258 nm for DF. In combination with DAD, an unambiguous identification in environmental samples is sometimes possible. However, the international agencies prefer methodologies which confirm identity using MS. The direct flow injection thermospray (TSP) MS of DQ and PQ demonstrates that the addition of a volatile buffer salt to the mobile phase is necessary because it provides a strong increase in sensitivity.

The problem of coupling HPLC with MS detection to determine ammonium quaternary compounds is that nonvolatile ion-pairing reagents are used to facilitate chromatography. These reagents contain insoluble sodium and potassium salts, phosphate and sulfonates, which are not amenable to MS confirmation of ammonium quaternary compounds, because these salts quickly precipitate and clog the HPLC/MS interface. Yoshida et al. and Barcelo et al. characterize PQ, DF, DQ, MQ and CQ by HPLC/TSP/MS. Under RP conditions and using ammonium formate or ammonium acetate as ionizing additives, 1–2 µg of each compound was positively identified under full scan conditions. For the characterization of DF, a postcolumn ion-pairing extraction system was used. An aqueous mobile phase with sulfonate-type counter ion was applied and an extraction solvent containing cyclohexane–dichloromethane–n-butanol was used in HPLC/TSP/MS. An HPLC method compatible with particle beam (PB) MS for DQ and PQ confirmation has also been developed; it ensures correct identification and quantification of both compounds.

An analytical method for the determination of MQ residues has also been reported. The final separation and determination is based on ion-pair chromatography using a column switching system and CD.

An HPLC chromatographic method for the simultaneous determination of the dinitroaniline herbicides dinitramine, ethalfluralin, tr trifluralin, pendimethalin and isopropalin has been proposed. In order to achieve the separation of dinitroaniline herbicides, different RP (C1, C8, C8, octadecysilica) ODS-1 and ODS-2) columns were employed. Each column allowed separation of the five herbicides with different water–acetonitrile mixtures. The elution order was the same (first and last, respectively) for dinitramine and isopropalin on all the columns tested, whereas ethalfluralin, trifluralin and pendimethalin were eluted with different orders in the different columns.

Analytical procedures have also been described for the trace analysis of oryzalin and prosulfalin residues in soil using an optimized HPLC system. The method requires no derivatization.

HPLC has recently been shown to be useful for trace analysis of a number of pesticide residues. Pendimethalin, chlorpyriphos, and the two esters 2,4-DIOE (isoctyl ester of (2,4-dichlorophenoxy)acetic acid) and 2,4-DPBE (butoxyethanol ester of 2-(2,4-dichlorophenoxy)propionic acid) were quantified by HPLC using a C18 column, a methanol–water (82:18) mobile phase and UV detection.

HPLC methods allow direct determination of chloroacetamides and their metabolites by UV and/or ED (electrochemical detection). As a complementary technique, HPLC/DAD can be employed for confirmation of these herbicides only if there is sufficient quantitative enrichment.

HPLC/MS/MS has been used to detect and identify alachlor, its ethanesulfonate metabolite, and its hydrolysis product 2,6-diethylalanine in water and urine. One relatively new method for analyzing herbicides in water involves using HPLC coupled with MS by means of electrospray ionization (ESP). The technique has been applied to the trace analysis of oxanilic and sulfonic acids of acetochlor, alachlor and metolachlor.

Chiral HPLC using modified cellulose and phenylglycine columns also showed some isomer resolution and was used for the isolation of acetochlor and metolachlor. The (+) and (−) enantiomers were assigned to acetochlor and metalaxyl using chiral HPLC in combination with chiroptical detection.

Clethodim herbicide has been separated from acid and photodegradation products (PDPs) by HPLC. Using an adequate mobile phase gradient, 31 peaks were separated following photocatalysis, as illustrated in Figure 5. Addition of acetic acid to the mobile phase improved peak symmetry and HPLC separation. Sethoxydim and its major active metabolite, sethoxydim sulfoxide, has been determined by normal-phase high-performance liquid chromatography (NPHPLC) using a silica column and methanol–dichloromethane containing acetic acid.
The excellent water solubility and the high polarity of amitrole makes it impossible to determine by RPHPLC with the usual aqueous eluent. The retention behavior shows no separation between amitrole and the solvent peaks. It is well known that satisfactory HPLC separations can be achieved in presence of ion-pairing reagents like sodium dodecyl sulfate (SDS), sodium butanesulfate and tetrabutylammonium sulfate. Figure 6(a) is a chromatogram corresponding to an injection of a solution containing 50 µg L⁻¹ of aminotriazole, and Figure 6(b) of a solution containing 0.5 mg L⁻¹, where the separation between solvent peak and amitrole is accomplished with SDS. The separation has also been done by NPHPLC on a polar cyanopropyl-column using hexane, propanol, water with LiClO₄ and trichloroacetic acid as electrolytes or using ion exchange chromatography.

The direct UV detection of amitrole suffers from a fairly low absorption coefficient and cannot be used. For greater sensitivity, derivatives of amitrole have to be formed by diazotization by coupling with 1-naphthol-3,6-disulphonic acid. Without a prior derivatization step, amitrole is directly detectable by an amperometric technique following ion-pair HPLC separation and coulometric electrode array detection (EAD). HPLC with UV after derivatization and ED required enrichment steps for the determination of concentrations in the range of 0.1 µg L⁻¹. Samples with concentration up to 1 µg L⁻¹ can be directly injected. Using EAD, tap and well water with concentrations down to 0.1 µg amitrole L⁻¹ can be determined without any enrichment steps.

Thiazopyr was determined by HPLC/DAD in water. It was hoped that DAD would provide spectral information to augment confirmation of incurred thiazopyr and its metabolite residues. Unfortunately, there were no distinctive wavelength maxima that could be exploited for monitoring purposes.

Several methods for determining of underivatized fluridone in milk, animal tissues and crops by HPLC have been described. HPLC methods are advantageous in that they are rapid and avoid the use of hazardous derivative reagents.

Norflurazon and its initial soil metabolite can be determined using HPLC with fluorescence detection. The fluorescence properties of norflurazon dissolved in acetonitrile were examined previously. Adding water or acidifying the solution had no effect on the observed fluorescence. A method for measuring chloridazon with an HPLC microbore column and DAD has been reported.

The application of a simple RPHPLC/UV method for the determination of the contact herbicide pyridate and its main metabolite CL9673 has been described.

Acta., 284, 317–326. Copyright (1993) with permission of Elsevier Science B.V.)
Amperometric detection has also been reported for the metabolite.\(^{(140)}\)

### 5.3 Immunoassay

Immunoassay offers certain advantages over conventional instrumental methods for the analysis of pesticide residues. Immunoassays are highly efficient and cost effective and are ideally suited for screening large numbers of samples for low levels of specific analytes.\(^{(195)}\) An enzyme immunoassay uses either a labeled antibody or a labeled analog of the target compound as the detection marker and can be performed in different formats. The most common format is the competitive enzyme-linked immunosorbent assay (ELISA). In competitive ELISA, the antibodies specific to the analyte are immobilized onto a solid phase. The enzyme–hapten conjugate and the analyte are added to the antibody-coated tube or plate for incubation. After incubation, the unreacted material is removed, and a substrate and chromogen are added and allowed to react for a short period of time during which the enzyme converts the substrate-chromogen to a colored product. The absorbance can either be measured with a spectrophotometer or estimated visually.

In some ELISAs the solid phases employed are polystyrene wells, balls or tubes, on which the antibody or hapten–protein conjugate are passively adsorbed. The desorption or leaching off of antibody or other proteins which have been passively adsorbed is a major factor that adversely affects sensitivity and precision assays. Variability of wells within microtiter plates has been shown to be the greatest contributor to total assay imprecision. A particle-based ELISA eliminates these imprecision problems through covalent coupling of antibody to the solid phase. The uniform dispersion of particles through the reaction mixture allows for rapid reaction kinetics and precise addition of antibodies.\(^{(169,170)}\)

A competitive ELISA for the quantification of free PQ cation was developed using polyclonal rabbit antiparaquat antibodies bound to a magnetic particle solid phase.\(^{(74)}\) The immunoassay described utilizes a competitive format. Since enzyme-labeled PQ competes with the unlabeled (sample) PQ cation for the antibody sites, the color developed is inversely proportional to the concentration of PQ cation on the sample. The speed and sensitivity of the method makes it suitable for large numbers of samples in short periods of time.

A carboxylic derivative of metolachlor, \(N\)-(chloroacetetyl)-\(N\)-(1-methyl-2-methoxyethyl)-2-methyl-4-(4′-carboxybutoxy)-6-ethylaniline, was synthesized and covalently linked to a carrier protein to prepare monoclonal antibodies. An antibody with high binding affinity for metolachlor was used to develop two competitive ELISA procedures, a direct one with enzyme-labeled antigen and an indirect one with an enzyme-labeled second antibody.\(^{(186)}\) No cross-reactivity was observed with alachlor, furalaxyl, metalaxyl, and most of the metabolites of metolachlor and metalaxyl.

Antibodies against alachlor were generated using an alachlor–protein conjugate. Alachlor was conjugated to the protein carrier through the chlorine-bearing carbon via a thioether bond. This type of linkage was easily obtained because of the reactivity of the chlorine-bearing carbon with nucleophiles such as glutathione. Furthermore, the sulfur atom facilitates the formation of antibodies that recognize alachlor. Conjugation of alachlor to proteins via the thioether linkage is a simple one-step reaction requiring no synthesis of novel haptens.\(^{(123,172)}\) Rabbit polyclonal antibodies generated using the thioether conjugate were useful in the development of a sensitive alachlor ELISA. The ELISA discriminated alachlor from other chloroacetanilide herbicides, although strong cross-reactivity was detected with some thioether metabolites.\(^{(171,175)}\) Subsequently an analog of alachlor was conjugated to proteins through a carboxyl group in the methoxymethyl side chain. Antibodies from the carboxy–alachlor conjugate showed even greater specificity towards alachlor and discriminated against other chloroacetamides as well as alachlor thioether metabolites.

Using the same thioether conjugation method, ELISAs for other chloroacetanilines herbicides, metolachlor, amidochlor and butachlor, have been developed.\(^{(182)}\) These chloroacetanilide herbicides were easily conjugated to proteins via a thioether linkage.

The ELISA method was evaluated for the detection of alachlor in environmental water samples and was compared with an established GC/MS method. The results indicate that the alachlor ELISA can be effectively utilized as a primary screen to select environmental samples for confirmatory instrumental verification of the presence of alachlor at low parts per billion levels.\(^{(168,195)}\) However, an ELISA for the detection of alachlor or putative alachlor metabolites in human urine has been described and compared with HPLC analysis, and the two analytical methods gave results with statistically significant differences.\(^{(143)}\)

An automated flow-injection liposome immunoanalysis system was developed using alachlor as a model compound.\(^{(176–178)}\) The experimental system consists of an autosampler attached to an immunoreactor column containing antialachlor antibody covalently coupled to glass beads.

The utility of immunoassay techniques as part as groundwater monitoring/compliance programs has been evaluated.\(^{(166)}\) There are several commercially available kits for determining chloroacetamides.\(^{(121,122,174)}\) The
results provide evidence that immunoassay techniques are simple and suitable. However, false positives should be tested for possible metabolites that may cross-react with the antibody.173,187

5.4 Other Techniques

5.4.1 Spectrometric and Spectrofluorimetric Methods

Methods for the determination of PQ and DQ by spectrophotometry have been reported. The spectrophotometric methods most often used are based on their reduction in alkaline solution. Reduction of PQ with sodium dithionite forms a blue reaction product73,90,92 and reduction of DQ forms a green71 or red one.88 Ascorbic acid65,72 or sodium borohydride93 also form a blue free radical ion with an absorbance maxima at 600 nm with PQ. PQ and DQ can be determined simultaneously using second-derivate spectroscopy after reduction with NaOH dithionite solution.65,87

It should be noted that the reaction product formed with DQ and dithionite is also fluorescent and can be measured using an excitation wavelength of 428 nm and an emission wavelength of 497 nm.71 Determination of DQ by photokinetic methods has been described,59,78 it is based on the rate of photoreduction of DQ by ethylenediaminetetraacetic acid (EDTA) sensitized by acridine yellow in absence of oxygen78 or on the formation of a charge-transfer complex between DQ and cysteine.59

5.4.2 Thin-layer Chromatography

The relationships between the structure of N1- or N4-substituted 1,2,4-triazoles and their behavior in thin-layer chromatography (TLC) on silica gel were studied. Linear correlations were obtained between the retention parameter, \( R_m \), and the logarithm of the molar fraction of a strong solvent in eight binary solvent systems for five pairs of positional isomers.65 Detection using 2-dichloromethylbenzoimidazole as the reagent on TLC has been described.132 A study on the adsorption and dissociation of the herbicide amitrole has been performed using radiolabeled compounds and TLC.127

5.4.3 Supercritical Fluid Chromatography

SFC is a suitable technique for determining azadirachtin in crude extracts of neem. Almost all the accompanying substances are less polar than azadirachtin and are eluted quickly. On the RPHPLC they elute very slowly and must be removed by pretreatment. The UV absorbing peak for azadirachtin can be separated from the other substances present in a relatively short time.12,56 Figure 7 shows the chromatograms obtained by SFC and HPLC. The chief differences between SFC and HPLC were the much longer time required for an HPLC separation and the much larger volume of solvent required.

5.4.4 Capillary Electrophoresis

CE techniques have proven to be promising alternatives to the separation and/or analysis of various ionogenic pesticides. Separations in CE are based on differences in the electrophoretic mobility of the injected ions. Tomita et al.91 have described the use of CE to determine PQ and DQ. The optimal conditions for CE separation of DQ, PQ and DF are well established14,69,75,147 and have been compared with HPLC determination.60 CE was simpler and cheaper, but HPLC offered a higher sensitivity for real samples and was independent of the matrix effects. Investigation into the application of indirect UV detection in CE published by Galceran et al.146 showed the suitability of an absorbing carrier electrolyte for the determination of the nonabsorbing quats, CQ and MQ, and also the simultaneous detection of the

---

**Figure 7 Chromatograms of triterpenoids found in neem seeds.** (a) SFC and (b) HPLC. Peak identification: (1) nimbin, (2) salamin, (3) 6-desacetyl nimbin, (4) 3-desacetyl salamin, (5) 3-tigloylazadirachtol, (6) azadirachtin, (7) azadirachtin-D, (8) 3-acetylt-1-tigloylazadirachtin, (9) azadirachtin-H, (10) salanninolide, (11) azadirachtin-I. The structure of the compound SL2 has not been determined. The peak areas do not represent their natural abundance in seeds, as the minor components have been enriched to make them more easily visible. (Reproduced from S. Johnson, D. Morgan, J. Chromatogr. A., 761, 53–63. Copyright (1997) with permission of Elsevier Science B.V.)
absorbing quats. Figure 8 shows the electropherograms obtained at the optimal conditions, 10 mM PP (pH 2.5) 10% MeOH. Applied potential, +20 kV; hydrodynamic injection, 5 s, at different detection wavelengths. Standard solution: PQ, 19.6 µg mL⁻¹; DQ, 37.3 µg mL⁻¹; EQ (ethyl viologen), 38.0 µg mL⁻¹; CQ, 25.2 µg mL⁻¹, MQ, 25.5 µg mL⁻¹, DF 27.6 µg mL⁻¹. * Negative peak (the arrows indicate a data acquisition interval time during which a negative peak is reversed and plotted as a positive peak). (Reproduced from M.T. Galceran, M.C. Carneiro, M. Díez, L. Puignou, J. Chromatogr. A., 782, 289–295. Copyright (1997) with permission of Elsevier Science B.V.)

Figure 8 Electroferograms obtained under optimal conditions, 10 mM PP (pH 2.5) 10% MeOH. Applied potential, +20kV; hydrodynamic injection, 5s, at different detection wavelengths. 5.4.5 Voltammetry

PQ and DQ have been determined by square wave voltammetry (SWV). This method is nonselective because the PQ and DQ species were reduced at the same potential values. However, these compounds present similar toxicities and are often used in mixtures, so that cumulative residue analysis is needed.

An electrochemical study of the chloridazon oxidative process in a silica-modified carbon paste electrode in Britton–Robinson buffer (pH = 11.30) using different voltametric techniques has been carried out. An oxidation wave is obtained at 900 mV and the system is irreversible and controlled mainly by adsorption. No interference of other herbicides has been observed and good results were obtained when this method was applied to the determination of chloridazon in soils.

5.4.6 Other Characterization Methods

The chloroacetanilide herbicides acetochlor, alachlor, butachlor, propachlor and metolachlor and their sulfonic acid metabolites were studied by nuclear magnetic resonance (NMR) spectroscopy and fast atom bombardment mass spectrometry (FABMS). Although similar in structure, the sulfonic acid metabolites were successfully characterized.

Fiber optic evanescent wave spectroscopy (FEWS) is a technique which allows in situ mid-infrared (MIR) absorption spectroscopy to be carried out in aqueous environments. The potential of this technique for monitoring alachlor at parts per million levels demonstrated that it can be employed as an alarm level indicator.

6 FOOD AND ENVIRONMENTAL APPLICATIONS

6.1 Macro cyclic Lactones

Zeng et al. studied cytochrome P-450 isoforms responsible for the metabolism of abamectin and ivermectin in the rat. The conclusions presented are based on results from incubation with liver microsomes from induced rats. The enzymatic activity of the cytochrome P-450 had been induced to increase the metabolism of the abamectine because of the limited quantities of metabolites produced by liver microsomes from untreated rats. The study was performed using radiolabeled compounds and metabolite profiles were determined by RPHPLC. One-minute fractions of the column eluate were collected into miniscintillation vials and mixed with a scintillation cocktail. The radioactivity of these samples was determined by scintillation spectrometry.

Information on residue levels, dissipation rates, and translocation resulting from a field treatment with 3H-avermectine B₁ was applied to orange and lemon fruits and lemon leaves. Whole fruit residues of avermectin at harvest are less than 0.001 ppm. (Translocation from
the treatment sites is so low as to be undetectable. Because of short persistence, avermectin should cause minimal environmental and food contamination.

Aerobic and anaerobic incubation of microbially active soil with $^{14}$C-emamectin benzoate resulted in measurable evolution of $^{14}$CO$_2$. Chromatographic and mass spectral analysis of extractable residues demonstrated the degradation of the compounds.\textsuperscript{(9)} The degradation in soils follows biphasic kinetics and is relatively rapid between days 0 and 60, becoming less rapid between days 120 and 360. The results of this study demonstrated that emamectin benzoate is biodegradable in soil, forming multiple residual products, and is eventually incorporated into soil components and mineralized to CO$_2$. Laboratory studies of the fate of $^{3}$H-labeled avermectin B$_{1a}$ in Lufkin fine sandy load, Houston clay and coarse sand demonstrated that under aerobic conditions the compound was degraded at a fairly rapid rate to at least 13 radioactive products.\textsuperscript{(21)}

Emamectin benzoate and its $\delta$ isomers were determined in a lettuce and celery field trial.\textsuperscript{(45)} The emamectin benzoate level dissipated rapidly on days 0–1 of the postapplication period and then dissipated thereafter at a slower rate. At seven days post-treatment, emamectin benzoate residues were not detected.

Rapid uptake of $^{3}$H-emamectin benzoate by bluegill sunfish was observed. The steady-state bioconcentration factors indicate that emamectin benzoate neither bioconcentrates in individual aquatic organisms nor biomagnifies in the food chain.\textsuperscript{(47)}

### 6.2 Chloronicotinyls

Determination of imidacloprid in water, after hydrolysis in basic medium, followed by GC/MS in SIM mode has been applied to groundwater samples from Santa Maria farm, near Granada (Spain) and in tap water from the city of Granada itself. Imidacloprid was not found above detection limit (0.16 $\mu$g L$^{-1}$).\textsuperscript{(53)}

Imidacloprid residues have been extracted from vegetables and determination was performed by HPLC/DAD. Fifty-four vegetable samples (peppers, tomatoes and cucumbers) with incurred residues from three different greenhouse plantations, treated with Confidor\textsuperscript{®} 20 LS (Bayer; 20% (w/v) of imidacloprid) at different doses and collected during the week after treatment, were selected to evaluate the effectiveness of the proposed method. Residues of imidacloprid were found in all samples in the 0.01–0.3 mg kg$^{-1}$ range.\textsuperscript{(52)}

The behavior of insecticide imidacloprid in rice and cucumbers was determined by HPLC/UV. The method was applied to determine the residues and rate of disappearance of imidacloprid from rice (nursery box treatment, 1 g of active ingredient/1800 cm$^2$) and cucumber plants (stem injection, 20 $\mu$g of active ingredient per plant). The insecticide incorporated into the plants decreased rapidly with a half-life of less than 3 days. In the rice, however, it controlled the brown planthopper even 60 days after application, with the marginal concentration of 0.01 mg kg$^{-1}$.\textsuperscript{(4)}

### 6.3 Tetranortriterpenoids

The neem tree, originally from India and Pakistan, has received much attention, thanks to the many valuable insecticide properties of azadirachtin. The compound is not easily separable from the many compounds of similar structure and polarity, of which over 100 have been isolated. The quantitative determination of the natural insecticide azadirachtin in crude extracts of neem seeds can be carried out by packed column SFC, with detection by UV absorption at 210–220 nm using CO$_2$–methanol as the mobile phase.\textsuperscript{(12)} Almost all the accompanying substances are less polar than azadirachtin and elute quickly.

The HPLC procedures for the quantitative determination of azadirachtin in an insecticidal formulation utilize detection with UV absorption at 215 nm. Formulations from neem kernels may contain additional constituents such as triglycerides, fatty acids and surfactants which can interfere with chromatographic analysis. Separation of the interferences is a prerequisite for analysis.\textsuperscript{(22,57,58)}

The hydrolysis of azadirachtin was studied in several natural waters. Azadirachtin appeared to be more susceptible to hydrolysis than synthetic organophosphates. Accordingly, azadirachtin is expected to be nonpersistent in water.\textsuperscript{(13)}

The stability of azadirachtin was examined in six common organic solvents (chloroform, acetone, ethyl acetate, acetonitrile, methanol and ethanol) to help in the development of formulations.\textsuperscript{(56)}

### 6.4 Ammonium Quaternary Salts

Both CE and ion-pair RP-HPLC have been used for the determination of PQ, DQ and DF. Ion pair RP-HPLC offers greater sensitivity for determination of herbicides in crop waters. The results obtained show that three samples contained PQ.\textsuperscript{(60)}

Analysis of DQ, PQ and DF in water has been performed using SPE on silica cartridges followed by NPHPLC determination. To show the applicability of the method in routine analysis of natural waters, three samples were taken from three different places in the Valencian Community (Spain): from irrigation channels of Ribarroja del Turia, El Palmar and Puçol with chemical oxygen demand (COD) values of 1.4, 3.9 and 12.0 mg O$_2$ L$^{-1}$, respectively. DQ was found in the El Palmar and Ribarroja del Turia samples at concentrations of
6 and 13 µg L\(^{-1}\), respectively\(^{(63)}\). An automatic sample preparation device (OSP (on-line sample preparatory), Merck) was employed to determine these pesticides. The procedure was applied to monitor the three herbicides in drinking and surface water. DQ, PQ and DF were not detected in drinking water. Twelve surface water samples from the natural park of L’Albufera (València, Spain) were analyzed. The pesticide presence was detected in four samples at concentrations ranging from 0.4 to 0.8 µg L\(^{-1}\)\(^{(64)}\).

An on-line SPE coupled with an HPLC procedure has been developed to determine DQ, PQ and DF in water, using GCB for extraction and determination\(^{(66)}\). Four surface waters from Torreblanca Natural Park (Castelló, Spain) were analyzed. Pesticides were found in three of the four samples at levels between 0.1–0.25 µg L\(^{-1}\) after passing 50 mL of water into the extraction cartridges.

Various techniques are used to improve contact of aquatic herbicides with submerged weeds to facilitate control. One commonly used method is to add one of a group of adjuvants, known as polymers to the spray tank mixture. Information on how these adjuvants affect herbicide distribution will be helpful for predicting movement of DQ from treated areas. DQ was applied in a lake to three 1.6 ha plots either with a polymer, which reportedly aids in sinking and confinement of aquatic herbicides, or without a polymer\(^{(62)}\). DQ was analyzed by extraction with C\(_8\) and ion-pair RPHPLC. Forty-six percent of the samples collected at the edges of the plot did not contain detectable DQ residues and only 66% of the sample with detectable DQ contained more than the drinking water tolerance (10 ppb).

A method for measuring CQ based on an in vitro multistep reaction by which CQ is initially N-demethylated and then derivatized was proposed\(^{(82)}\). ECD and MS were used to analyze cotton seed harvested from cotton plants treated with various concentrations of CQ. Concentrations between 0.01 and 1.0 µg g\(^{-1}\) were determined with a limit of detection of 0.003 µg g\(^{-1}\).

The herbicides DQ and PQ can be analyzed in edible oils by HPLC/UV at 210 nm using an ODS column. Recoveries from 90 to 93% can be obtained with a pH 7 aqueous phosphate buffer extraction procedure and cleanup with C\(_{18}\) cartridges. Only two of the 12 analyzed virgin oil samples from olive crops sprayed with these herbicides contained DQ residues\(^{(83)}\). A photokinetic method based on photoreduction with EDTA and acridine yellow using polarography has been applied to DQ in potatoes. The concentration of DQ found in the potatoes ranged from 13.74 to 24.51 µg g\(^{-1}\)\(^{(78)}\).

A spectrophotometric method for the determination of PQ using a reducing agent was described\(^{(93)}\) using sodium borohydride and alkaline medium to give a blue radical ion with an absorbance maximum at 600 nm. The method was applied to the determination of PQ in human samples, such as blood, urine and mother’s milk compared to food and environmental samples.

### 6.5 Dinitroanilines

Studies were undertaken to evaluate the dissipation of pendimethalin in two Canadian field soils following application of an emulsifiable concentrate formulation in the spring. Residues of pendimethalin were determined by extraction with acetonitrile and GC/ECD. Over a longer period there was no leaching of the herbicide below 10 cm\(^{(101)}\). Residues of pendimethalin were carried over in soils to the next crop year in amounts between 12 and 28% of that applied (1.11 kg ha\(^{-1}\)).

Pendimethalin, alachlor and metolachlor were often found to be present in rainfall in Indiana and Ohio. Analysis was performed by GC with dual-column using NPD\(^{(154)}\). Concentrations were in the range 0.1–1.0 µg L\(^{-1}\). During periods of frequent or prolonged rainfall, concentrations decreased sharply. Concentrations in the next rainfall generally were higher that those at the end of these periods, consistent with a scavenging effect of precipitation on the local atmospheric load of these compounds.

A method based on the extraction of soil samples in small columns has been used for the determination of pendimethalin and other herbicides in soil. Soil samples from experimental fields taken at different times after treatment from the low layer were analyzed and the values were similar to those obtained using a conventional LLE method\(^{(153)}\). Soil from experimental fields treated with pendimethalin was sampled at various times. A concentration of about 3 µg g\(^{-1}\) was found at the beginning of the application. One month later the concentration decreased to 1.2 µg g\(^{-1}\).

### 6.6 Acetamides

Determination of the ethanesulfonate metabolite of alachlor was performed by RPHPLC/UV\(^{(104)}\). Eleven water samples (ground and surface) collected from Indiana and Ohio were analyzed. Of these 11 samples, 9 were shown by HPLC to contain ethanesulfonate varying in concentration from 0.6 to 74 ng mL\(^{-1}\).

SPE was combined with HPLC and electrospray ionization mass spectrometry (ESIMS) for the trace analysis of oxanic and sulfonic acids of acetochlor, alachlor and metolachlor. The isolation procedure separated the chloroacetanilide metabolites from the parent herbicides during the elution from C\(_{18}\) cartridges using ethyl acetate for parent compounds followed by methanol for the anionic metabolites\(^{(109)}\). Concentrations in the nanogram per liter range were found in surface and groundwater.
samples. Extraction of butachlor with XAD-2 resin and determination with GC/ECD was described.113 Pesticide residues in river and surface waters can be identified and determined. Residues of butachlor were frequently detected when it was applied to control the weeds in flooded paddies but the results indicate that the herbicide was not persistent in the aquatic environment.

A method for determining trace levels of butachlor, pretillachlor, and other herbicides in river water has been developed. The method is based on C_{18} SPE, followed by GC/MS/SIM.103 Recoveries at the 0.5 or 2.5 µg L\(^{-1}\) fortification level were between 79 and 98%. The detection limits were 0.01 µg L\(^{-1}\). The analytical findings on surface water samples collected from rivers indicated that most of the pesticides were detected in river water at 1–10 µg L\(^{-1}\) levels during the first 2–4 weeks after application in the fields. A similar method was reported for determining alachlor, butachlor and other herbicides in a dissolved and suspended phase of river water.112 This method was applied to monitor herbicides in river water from the Shinano River (Japan). Butachlor was detected in some filtered water samples.

A method for the simultaneous identification of neutral and acidic pesticides in natural water\(^{114}\) includes enrichment of the compounds by SPE on GCB, followed by sequential elution of the neutral and acidic pesticides and derivatization of the latter fraction with diazomethane. Identification and quantification of the compounds was performed by GC/MS. The method has been used to analyze various natural waters including rainwater, roof runoff, surface water and groundwater. Alachlor was frequently detected in rainwater and runoff water during the application period of pesticides. Concentrations were 16 ng L\(^{-1}\) and 19 ng L\(^{-1}\), respectively.

Heyer et al.\(^{105}\) describe SPE with RP-C\(_{18}\) adsorbent for the analysis of alachlor and the development of a micro LLE method following GC/ECD and NPD determination of alachlor and its metabolites DEA (2,6-dimethylamine) and CDEA (2-chloro-2',6'-diethylaniline). Both methods were applied to the analysis of more than 200 groundwater samples during a field study and gave similar results. The concentration of alachlor was around 0.5 ng L\(^{-1}\). Degradation products of alachlor were not found in the field study.

Atrazine, propachlor, butachlor, metolachlor, alachlor and two alachlor products were determined in water, also using a micro LLE.\(^{25}\) The method involves a one-step extraction of water samples with n-hexane followed by direct analysis of extracts using GC/NPD or GC/MS. The analytes detected in the five groundwater samples included alachlor (0.1–1.2 µg L\(^{-1}\)) and metolachlor (0.1–2.5 µg L\(^{-1}\)). The target alachlor degradation products were not detected in these analyses.

The corn herbicide acetochlor was detected and analyzed by GC/MS. The concentrations and fluxes of acetochlor in rain and in the Blue Earth River in Minnesota were reported. Acetochlor was consistently observed and the concentrations in both rainwater and the river were in the 10–250 ng L\(^{-1}\) range in most samples.102

A combination of HPLC/DAD and GC/NPD with UV and MS confirmation, respectively, has been applied to the determination of trace levels of herbicides in relatively clean water samples by LLE. Illustrative examples of the determination of several herbicides in estuary water samples from the Ebro Delta (Tarragona, Spain) are shown. Alachlor and metolachlor were the most commonly found acetanilides, with concentrations levels varying from 5 ng L\(^{-1}\) to 5 µg L\(^{-1}\).

Analysis of alachlor was performed by immunoassay using EnviroGard\(^{\text{TM}}\), and 67 well samples were analyzed. Alachlor was contained in many samples that are positive by immunoassay. In fact, of the 18 positive well samples by immunoassay, just six were found to have alachlor by HPLC.\(^{116}\)

SPE and ELISA were combined for the trace analysis of the herbicide alachlor and its major soil metabolite ethane sulfonic acid. These compounds were isolated from water by SPE on C\(_{18}\) and eluted sequentially with ethyl acetate and methanol. Analyses of surface and groundwater samples were confirmed by GC/MS and HPLC/DAD. Results showed widespread occurrence of ethane sulfonic acid in the midwestern USA, with concentrations ranging from <0.10 to >10 µg L\(^{-1}\).171

The ELISA method was evaluated for the detection of alachlor in environmental water samples and was compared with a GC/MS method. In analyses of environmental water samples ELISA was less accurate and precise than GC/MS.\(^{116}\)

Unexpectedly high frequencies of positive responses were observed in ELISA screening for alachlor in private rural wells, when samples were analyzed using the EnviroGard\(^{\text{TM}}\) Alachlor Plate Kit. The majority of the positive responses were false positives with respect to alachlor. In the false positive samples, most appear to be due to the ethanesulfonate metabolite of alachlor. Confirmation testing for alachlor used SPE and analysis by GC/MS. A method using SPE and HPLC/UV was developed for the analysis of the metabolite.\(^{117,175}\)

An immunoassay for detecting alachlor or putative alachlor metabolites in human urine has been developed and compared with measurements obtained by HPLC analysis of urine hydrolyzate for DEA.\(^{113}\) Twenty applicators and seven hauler/mixers participated in the study. Also, eight employees of the application companies who were thought to have limited exposure to pesticides submitted urine samples for alachlor dose estimation. The ELISA and HPLC analytical methods gave different
results because the metabolism and excretion of alachlor is not well defined.

Human alachlor exposure has commonly been estimated by quantifying the hydrolysis product DEA, of alachlor metabolites in urine. The alachlor metabolite was identified by using HPLC/MS/MS to analyze extracts of urine samples from subjects who were occupationally exposed to alachlor.

Several herbicides widely used to control weeds in corn (atrazine, alachlor, metolachlor and pendimethalin), have been determined in soil and water. Analysis of herbicides was performed by GC/NPD and GC/MS. Soil samples from corn fields after harvest were taken in several fields located in Spain and water was taken from wells located in the fields. Herbicides were not detectable in water samples from one well, but in another well alachlor was detected at levels higher than 0.1 ppb. In soil, residues varied in the different fields and were in some cases higher than 0.1 µg g⁻¹.

An ethanesulfonic acid metabolite of metolachlor was identified in soil sample extracts by FABMS and FABMS/MS. A dissipation study revealed that ethanesulfonic acid is formed in soil under field conditions corresponding to a decrease in the concentration of the metolachlor.

6.7 Oximes

Several analytical methods have been described for determination of alloxynim sodium, sethoxydim and its major active metabolites and clethoxidim. Results obtained after application to residue determination in real samples are not reported.

6.8 Triazoles

An HPLC method with amperometric detection was described for determining residue levels of amitrole in drinking and groundwater. Samples with concentrations up to 1 ppb can be injected directly. When a simple evaporation enrichment step is used, the limit of determination is 0.1 ppb. If the method is applied to groundwater samples, no interference from co-eluting constituents appears in the chromatograms. Another method using a coulometric array detector was also applied to tap and well water samples. Concentrations of amitrole down to 0.1 µg L⁻¹ can be determined without any enrichment steps. Several well water samples were investigated. Amitrole was not detectable.

Amitrole can be extracted with ethanol, adsorbed on resin and desorbed with ammonia. After acetylation with acetic anhydride and cleanup over a Sep-Pack™ silica cartridge, the amitrole-acetyl derivative was determined by GC with FPD (flame photometric detection) in plant tissues and sandy soils. The method was used for screening the abuse of amitrole on vegetation growing on sandy soils. Over a period of more than one year a wide variety of weeds was analyzed.

6.9 Pyridine-based Molecules

Thiazopyr residues have been determined in soil, grass weed and seedlings of woody plants after extraction with ethyl acetate, cleanup on a Florisil™ column and determination by GC/NPD and confirmation by GC/MS with ion trap detection. The proposed method was applied to the determination of the herbicide level in treated soil and plant samples. The concentration range was 0.2–1 ng g⁻¹.

7 CONCLUSIONS

Miscellaneous pesticides are mainly polar compounds. For this reason, HPLC is the preferred technique for their separation and determination. However, complicated derivatization schemes are still used to enhance sensitivity and selectivity. These derivatization reactions present several problems when environmental analyses are performed or many samples are processed because they are time-consuming and give rise to interferences caused by the reagents and endogenous compounds of the matrices.

Best extraction methods should be used in order to obtain better separation of the endogenous interference compounds from the matrix and better sensitivity. Extraction methods using SPE are rarely employed in the analysis of miscellaneous pesticides. The use of these methods would make it possible to incorporate on-line extraction procedures, and to include these pesticides in the general multiresidue systems employed to determine a wide range of pesticide varieties from several matrices.

The development of modern techniques will facilitate application to real samples, monitor the presence of the pesticides in the environment and establish their persistence, fate, degradation and risk on the basis of real field data.

Contamination of water by pesticides is an important issue in many regions, posing problems in the environmental, water management and health sectors. To assess the extent of contamination of water, effective and properly designed analytical methods having sufficient sensitivity and accuracy are needed. However, no matter how excellent are the state-of-the-art analytical instrumentation and techniques applied, the data on trace concentrations of pesticides provided by the analytical system will be useless unless sufficient attention is given to sampling and sample preparation.

To collect a representative water sample for pesticide analysis, all sampling parameters must be selected properly. This refers predominantly to the selection of the appropriate sampling site, sampling technique and volume of the water sample. To prevent the sample matrix from any undesirable alterations during its transport from the sampling site to an analytical laboratory, physical (e.g. temperature, light intensity) and chemical/biochemical (e.g. pH, microbial growth) conditions must be under control, i.e. the sample must be preserved carefully. An efficient alternative to the transport of liquid water samples from the sampling point to the laboratory is on-site sorption of analytes on a solid phase. This minimizes the weight of transported samples and increases the stability of analytes.

The determination of trace concentrations of pesticides in water samples and the complexity of environmental matrices require the application of an efficient sample-handling procedure prior to separation and detection of these analytes. At present, liquid–liquid extraction (LLE) and solid-phase extraction (SPE) are the most frequently applied sample-handling techniques in the determination of pesticides in water. LLE is a traditional method that is still widely used in standardized methods. The increasing popularity of SPE is a result of its versatility and effectiveness and SPE is also preferred owing to the lower health risks.

The introduction of new sorbent materials, the development of automated sample-handling systems allowing unattended operation and newly emerging sample-handling techniques such as solid-phase microextraction (SPME) and membrane separation methods guarantee that sample preparation in pesticide analysis will remain a fertile area of development in the future.

1 INTRODUCTION

The extent of the application of pesticides reaches many thousands of tons per pesticide annually in many countries and the diversity of the insecticides, herbicides, growth regulators, fungicides and other applied substances is increasing rapidly. This extensive application has a negative impact on the quality of the environment. Because of their widespread use, pesticides are currently detected by determination of their residues in various environmental matrices, especially water.

To prevent water pollution by pesticides, precise information on their concentration levels in the water environment is needed. Owing to the diversity of pesticides and their low concentrations in water, the acquisition of this information requires the development of effective and properly designed analytical methods. The initial part of any of these methods comprises sampling and sample preservation and preparation. While in the past the importance of these initial steps has often been neglected, it is now clear that any mistake that occurs in collecting and processing a water sample can lead to substantial errors in the final data, regardless of the excellent performance of the state-of-the-art analytical technique that may be applied subsequently. Moreover, the results of a survey among analysts indicated that, for all respondents, two-thirds of the analysis time was spent on collection and preparation of the sample.\(^1\) Therefore, it is clear that sample collection and handling deserves the attention of any water analyst who is trying to increase the throughput of methods used and to improve the overall performance of the analyses performed.
2 SAMPLING AND SAMPLE PRESERVATION

2.1 Sampling Site

The sampling site must be selected with respect to the objectives of a monitoring program or a survey. Thus, the overall monitoring strategy predetermines the choice of profiles in water streams or the number and/or the depth of the monitoring wells.

For instance, if the objective is to monitor transboundary pollution of the water stream, the location should be as close as possible to the border. If the objective is to assess the quality of water used for drinking-water production, the sampling site should be positioned close to the intake. The number and location of sampling stations for groundwater monitoring is a function of the objectives and scale of assessment (background or trend monitoring, emergency surveys around a spill, operational surveillance of the quality of potable water resources), the hydrogeological complexity and economic considerations.

In all those cases it must be assured that the location is suitable for taking representative samples with due regard for the objective of the sampling. Furthermore, to assure representativeness of the sample, it is recommended that replicate samples be taken occasionally to determine temporal and spatial variability. A thorough discussion on monitoring strategies is beyond the scope of this article and can be found in various manuals.\(^{(2–4)}\)

2.2 Sample Volume

Sample volume depends on the number of analyses to be performed and on the technical requirements of a particular analysis. The volume of the water sample required for a single analysis of pesticides usually ranges from tens of milliliters up to 1–2 L, depending on the methodology applied. Traditional gas chromatography (GC) or high-performance liquid chromatography (HPLC) methods, in which an aliquot of the extract of the water sample is analyzed, require processing of a large volume of water (500 mL to 2 L) in order to reach the desired sensitivity. For modern SPE procedures, several hundred milliliters of water sample usually suffice. Introduction of highly sensitive detectors, on-line SPE techniques and large-volume injection possibilities permitted the reduction of the sample volume required for one analysis down to tens or even units of milliliters.

The total volume of water sample to be collected from the sampling site depends on the total number of analytes to be analyzed. Hence, theoretically, it can vary from 10 mL when, e.g., atrazine in water is to be determined using an on-line SPE/HPLC method to 10 L and more when a complete pesticide survey is to be carried out using standard methods employing LLE. To cover a large range of pesticides requires the application of a large number of different target methods, which makes complex screening laborious. A solution is the use of a suitable combination of methods covering as much of the pesticide range as possible. This approach has been used in a National Pesticide Survey performed in the USA where seven analytical methods were used to cover more than 100 pesticides of interest.\(^{(5)}\)

2.3 Sampling

In general, the type of sampling depends on the goal of the monitoring program and differs for river water, reservoirs, groundwater, rainwater, wastewater, drinking water or pore water from the unsaturated zone. In river waters the sampling methods are usually based on bottle collection or water pump systems. When a homogeneous reach of a stream is monitored, the collection of samples in a single vertical mode may be sufficient. For small streams a grab sample taken at the centroid of flow is usually adequate.

For sampling profiles located on a nonhomogeneous reach of a river or stream, it is necessary to sample the cross-section of the river or stream at a specified number of points and depths. In principle, the cross-section has to be checked for homogeneity, analyzing a minimum of three locations within the cross-section, the left and right banks and the center of the river. Vertical homogeneity should also be checked. Sampling in streams should be normally performed at a depth of 0.3–1.0 m. Surface sampling is employed when there is a need to collect the heterogeneous matter floating on the river surface.

A similar situation is encountered in reservoirs, where the sampling design must take into account the vertical stratification. The presence of anaerobic conditions in the lower layers and algal growth in the surface layers leads to the establishment of specific distribution of physicochemical parameters in water influencing the stability and behavior of dissolved pesticides. Therefore, along with the pesticide analysis, data on basic physicochemical parameters such as temperature, pH, conductivity, nitrates, ammonia and oxygen should also be collected.

For sampling of groundwater, different kinds of pumps withdrawing the water from the boreholes or wells are used. Such discharge samples are normally collected in bottles from a well-head tap or directly from a pump outflow. In some cases grab sampling from nonpumping boreholes is also possible. The most common method of unsaturated zone sampling is by suction or tension. When taking samples from pump discharge, it must be ensured that the sample is representative of hydrochemical conditions in the aquifer, rather than those in the well.
In the case of public supply or irrigation wells which are operating continuously (or at least for long periods) at high discharge rates, it is relatively easy to collect a sample after a sufficiently long period of pumping to be certain that the water has been drawn from the aquifer rather than from within the well itself. If, however, specialist sampling pumps with low discharge rates are used to sample nonpumping observation wells, then purging the well of standing water is required before sampling.\(^5\) It is often recommended to purge the water by removing 3–10 well volumes. It is also advised to measure continuously selected physicochemical parameters (pH, conductivity, temperature) to detect when stable conditions have been reached, indicating that the required high proportion of aquifer water is being drawn.

Even for one particular matrix the type of sampling can vary depending on the character of the information that is to be obtained from the monitoring. There are principally two types of samples: grab samples and composite samples. A grab sample is taken at a selected location and time, and then analyzed for pesticides. The collection of grab samples is appropriate when it is desired (i) to characterize water quality at a particular time and location, (ii) to provide information about minima and maxima and (iii) to analyze parameters which can be subject to change. A composite sample is obtained by mixing several discrete samples of equal or weighted volumes collected at regular time intervals in one container, which is subsequently analyzed for the parameters of interest. Instead of discrete sampling the water sample can be pumped continuously and required volumes of the sample for the analysis can be abstracted from the total bulk. Continuous sampling is advantageous in the case of automated monitoring systems. The selection of an appropriate sampling strategy has a considerable effect on the information output from a monitoring campaign. Especially for pesticides with seasonal occurrence it is very important to determine a suitable frequency and overall scheme of sampling, otherwise large deviations in the assessment of annual mean concentrations can result.\(^7\)

To ensure that the collected water sample is a real representative of the sampled site and to avoid the detection of false positives, strict quality-control principles should be followed. These principles include qualification of sampling staff, checking for purity of sampling containers and collecting field blanks and field check samples. The use of duplicate samples for checking of sample stability and for eliminating random sampling errors is highly advisable.

### 2.4 Preservation of Water Samples

Preservation of the sample during transport and storage depends on the type of pesticides to be analyzed. In principle, we have to prevent any potential means of losses of analytes from the liquid phase, such as transfer to the gaseous phase (evaporation), transfer to the solid phase (adsorption on the container walls), hydrolysis, photodegradation and biodegradation. The losses due to analyte evaporation are not a critical issue for most pesticides. In any case, the storage of the water sample at 4°C, minimization of the volume of the gaseous phase in the container and the use of gas-tight caps is recommended. Hydrophobic pesticides can be easily adsorbed on polymer surfaces. From an aqueous sample containing highly lipophilic organic compounds that are stored in a common plastic bottle, more than 90% of these compounds can be adsorbed within 24 h. Therefore, the storage of water samples in plastic containers must be avoided and the use of glass vessels only is recommended. Many modern polar pesticides can easily hydrolyse when the pH reaches a certain critical value. Hence it is necessary to maintain the pH at a desired value using a buffer solution or, usually in the case of acidic compounds, simply by acidifying the water sample. Keeping the samples in the dark and using amber-glass sample containers when available should prevent photolysis of the analytes. The presence of bioorganisms in water leads to biodegradation of dissolved pesticides. To suppress the biological activity of the aqueous environment, biodegradation inhibitors such as HgCl\(_2\) are used.

Most standardized methods recommend reducing the time of storage of the water sample to a minimum and performing the extraction as soon as possible. Storage periods that are usually officially suggested range from 7 to 14 days. In the United States Environmental Protection Agency (USEPA) National Pesticide Survey, thorough analyte stability studies of both well water samples and final extracts were performed.\(^5\) The primary focus of these studies was to demonstrate the stability of analytes for the maximum sample and extract holding times that would be permitted during the survey. Up to 100% loss was observed for 26 out of the 147 pesticides spiked into well water samples which had been biologically inhibited and stored at 4°C for 14 days. The same pesticides generally remained stable in stored sample extracts.

An alternative to the transport of liquid samples is the on-site sorption of analytes on the solid phase, which minimizes the weight of transported samples and increases the stability of analytes. In many cases, the transfer of groundwater samples from an anaerobic aquifer to an aerobic environment may initiate oxidation or biodegradation of organic compounds, which may continue during the transport. Also, when taking a sample from an aerobic environment, photodegradation and biodegradation processes can alter the composition of the aqueous sample irreversibly. Using sorption
on a sorbent, analyte evaporation is minimized and adsorption on the container walls is avoided. Binding of molecules of the organic compounds to the active sites on the sorbent surface slows undesirable changes in their quality and quantity. Green and LePape\textsuperscript{8} observed that XAD-2 macroreticular resin and octadecyl-bonded silica (C\textsubscript{18}) had a preservative effect, which prevented the breakdown of sorbed hydrocarbons by bacteria. Hydrocarbons stored on these solid phases for periods of up to 100 days in the presence of an oleophilic bacterial population showed no evidence of biological degradation. In contrast, hydrocarbons stored in water samples containing the same bacteria showed pronounced degradation over much shorter storage periods. These authors suggested that the preservative effect resulted from trapping the organic compounds in the adsorbent lattice structure. The pores of XAD-2 or silica gel were smaller than bacteria, hence, the hydrocarbons were protected from bacterial attack. The stability of 34 selected pesticides extracted from water on to a graphitized carbon black (GCB) surface was evaluated under various storage conditions.\textsuperscript{9} The best results were obtained by first minimizing the water content in the GCB extraction cartridge by a suitable methanol washing and freezing the cartridge. Under these conditions and over a storage period of 3 weeks the stability of pesticides extracted from four river water samples on to the GCB surface was assessed and compared with that in water at 4°C with and without an inhibitor of biological degradation such as mercuric chloride. The results indicated that storage on the GCB material was a far better preservation procedure than storage in water at 4°C. Several of the pesticides considered were completely degraded when stored in water in the presence of HgCl\textsubscript{2}. Similarly to disposable off-line SPE cartridges, SPE precolumns were also tested for analyte storage possibilities. The stability of 19 organophosphorus pesticides was investigated using precolumns from the Prospekt (automated on-line SPE) system packed with C\textsubscript{18} and stored under different conditions.\textsuperscript{10} This study demonstrated that many organophosphorus pesticides that showed instability problems in water matrices were stable in disposable SPE precolumns for a period of up to 8 months at \(-20^\circ\text{C}.\) Similar cartridges were also used for the investigation of the stability of different groups of polar pesticides (triazines, phenylureas, carbamates and chlorinated phenols) sorbed on polymer sorbents from water samples.\textsuperscript{11} The results showed the stability of most of the tested pesticides stored in cartridges for 7 weeks at the laboratory temperature or in a refrigerator. In Figure 1 it can be seen that except for carbaryl the recoveries of all tested pesticides were in the range 80--120% within 7 weeks of storage, which is an acceptable variance in organic trace analysis. The differences between stability of analytes when stored on a wet or silica gel-dried sorbent were negligible. The pH value of the water sample had a significant influence on the stability of only those compounds

![Figure 1] Figure 1 Stability of pesticides sorbed from spiked tap water on to polymer cartridges that were stored wet in a refrigerator at 4--5°C. Stability is expressed as the change of chromatographic peak area with time.
which had acid–base properties. The results obtained with surface water were similar to those obtained with tapwater. Also, a new SPE material, membrane extraction disks, was found to be a good preservation medium for pesticides.\[^{12}\] The stability of triazines and acetanilides on these disks at \(-20\,^\circ{\text{C}}\) for 3 months, during which there was no evidence of degradation, indicated the feasibility of storage under these conditions. In general, in all of these stability investigations SPE was confirmed to be a suitable sample-handling technique when long-term preservation of analytes prior to the analysis was required.

### 3 SAMPLE HANDLING

Trace concentrations of organic analytes in water samples and the complexity of environmental matrices require the application of an appropriate sample-handling procedure prior to the separation and detection of these analytes. As has already been mentioned earlier, for contemporary environmental analysis it is characteristic that highly efficient separation and detection systems are often coupled with laborious and time-consuming sample-handling procedures which limit the sample throughput and hence the overall performance of the method.\[^{1}\] Hence, at present, sample handling is considered to be the weakest point in environmental chromatographic analysis. The methods of and approaches to the sample handling of pesticides in the aquatic environment have already been thoroughly reviewed by Barceló and Hennion\[^{13}\] and related reviews can also be found elsewhere.\[^{14–17}\]

The major reasons for the preparation of water samples prior to pesticide analysis are

- preconcentration of analytes in order to enrich the sample with traces of the analytes;
- removal or reduction of compounds that interfere in the separation and/or detection steps;
- transfer of analytes into a homogeneous liquid matrix amenable to chromatographic analysis.

In most cases the preconcentration factors required for the efficient analysis of pesticides at the environmentally relevant levels are 100–10,000. In addition, a sample-handling procedure must be sufficiently robust to provide reproducible data for different aqueous matrices with various properties. The selected sample-handling strategy usually depends on the aim of the analysis and on the information expected, i.e. whether the analyst wants to detect one or several particular compounds of interest (target analysis) or if a multiresidue screening of a wide range of pesticides is required. In target analysis, the sample-handling step employs more selective procedures and media and more attention is paid to cleanup techniques. In screening analysis, nonselective procedures are usually preferred and, when necessary, a combination of several sample-handling techniques can be applied simultaneously. For example, during a long-term international program on river pollution identification that was performed in the Nitra river basin,\[^{18}\] the simultaneous use of two LLE procedures along with an SPE method was performed to increase the "analysis window" as much as possible so that most of the organic pollutants present in the river water could be detected.

The complexity of a sample-handling procedure to be employed depends also on the type and level of the separation and detection system applied for this analysis. The use of a relatively nonselective detector or a chromatographic system with a low separation power in a target method requires the application of a selective trace enrichment procedure. On the other hand, a selective and sensitive detector used with a good separation system provides acceptable results even when a very simple sample-handling scheme is applied.

Nowadays, LLE and SPE are the most frequently applied sample-handling techniques in the determination of pesticides in water. The prevalence of LLE applications in environmental analysis in the past resulted from the hydrophobic character of pesticides listed on the priority pollutant lists at that time and also from the absence of an equally suitable and efficient technique. At present, LLE is still widely used in standardized methods for pesticide analysis, primarily those used for nonpolar pesticides. It is often preferred owing to the availability of standardized procedures and good descriptions in the analytical literature.

The increasing popularity of SPE is due not only to its obvious advantages over LLE (minimized consumption of organic solvents, no emulsion formation, reduced contact of the analyst with potentially toxic substances) but also to gradual refinements of this procedure which minimize its original drawbacks. The introduction of membrane extraction disks increased the speed of the preconcentration and the growing production of SPE materials lowered their prices. A wide choice of newly developed materials makes SPE perfectly suitable to cope with the growing variability of modern pesticides. At present, the major factors stimulating the preference of the use of SPE in water analysis are the possibility of automation, sample storage and preservation ability and a high potential in offering solutions for complex preseparation schemes.

The theoretical background of LLE and SPE is based on similar principles of the interphase distribution of a solute in a two-phase system. The distribution of a solute in such a two-phase system (liquid–liquid or liquid–solid)
is governed by the affinities of the solute to these phases and it is characterized by a distribution constant. In LLE, the transport of solutes from an aqueous phase into an organic solvent immiscible with water depends mostly on the hydrophobicity of the solute and its solubility in the solvent. In this case the preconcentration is carried out as a one-step transfer of the solute from water to an organic solvent. After equilibrium has been reached, an aliquot of the organic solvent is introduced into an analyzer. However, when needed, the solutes can be redissolved in another suitable solvent.

On the other hand, most SPE procedures comprise two-step transfer of the solute. First, the solute is sorbed from water on the solid surface of a sorbent or in the stationary phase bound to this surface and, subsequently, the solute is eluted with an appropriate solvent (or thermally desorbed into the gas chromatograph). Here, the choice of a suitable sorbent (i.e. the selection of strength of interactions responsible for binding the solute on the solid phase) and the choice of eluting solvent or thermal desorption conditions (i.e. the energy needed for breaking of the bonds) must be properly tuned to obtain a quantitative preconcentration.

### 3.1 Liquid–Liquid Extraction

In the 1960s and 1970s, the attention of environmental scientists was focused mostly on nonpolar pesticides which, thanks to the extensive implementation of electron-capture detection (ECD) in analytical practice, were found to be ubiquitous and owing to their accumulation potential they were recognized as a serious threat to the environment. Despite the excellent sensitivity of ECD, the preconcentration step was needed to reach low nanogram per liter levels, as was required by environmental standards. The strongly hydrophobic character of most of those compounds was a prerequisite for the choice of LLE as a preferred preconcentration technique that gave satisfactory recoveries for nonpolar pesticides.

Most of the classical preconcentration methods employing LLE have a relatively similar pattern: a water sample is extracted two or three times with a small volume (usually 10–50 mL) of an organic solvent (hexane, heptane, cyclohexane, methylene chloride, Freon, etc.) and the extracts (plus the solvent used for rinsing the internal surface of the glassware used for the extraction) are dried with purified sodium sulfate, filtered, evaporated either to dryness or to a volume usually under 1 mL and redissolved in a small volume of the solvent compatible with a selected chromatographic technique. This general pattern can, naturally, differ in various modifications and/or refinements of original methods but, in principle, three consecutive extraction steps with extraction volume ratios of approximately 1:30–40 are sufficient for removal of at least 90% of the hydrophobic compounds from water.

To remove interfering compounds, the extract can be cleaned by percolation through a column packed with Florisil, alumina or another suitable sorbent.

Many different methods for pesticide analysis involving LLE have been published in the past but the actual strength of LLE is the availability of a number of standard procedures. Examples of standard methods for the determination of different groups of pesticides in water using LLE are shown in Table 1. Moreover, LLE is used not only in standardized methods for the determination of specific groups of pesticides but also in broad-range methods covering a large number of priority pollutants. A great strength of common standardized LLE methods is that in addition to their standard description needed to achieve status as an official method, also the results of their interlaboratory validation can be found in the literature. These collaborative studies help in judging the acceptability of a particular method by characterizing its multilaboratory performance in terms of recovery, overall and single analyst precision and the effect of water type on recovery and precision. The availability of the results from an interlaboratory validation supports the reliability of a tested method.

Even though it may seem that in the field of LLE everything has been investigated and solved, there are still new approaches to be studied. The use of a Goulden large-sample extractor was tested to reach DLs in the low nanogram per liter range and this technique was presented as an alternative for SPE. The general strategy for multiresidue analysis of polar pesticides in groundwater using LLE with methylene chloride was published by Hoogendoorn et al. The extracts were cleaned up on-line by means of column switching and subsequently analyzed by step-gradient elution. This approach was found to be powerful for the simultaneous assay of polar pesticides.

The use of LLE also simplifies the problem of the determination of the total content of a hydrophobic organic compound in a water environment. This problem is relevant especially for surface-water samples with a high content of suspended solids. In an LLE procedure, an organic solvent extracts hydrophobic analytes from both the aqueous solution and solid particles suspended in the water. Rinsing of the glassware minimizes the losses of analytes caused by adsorption on the glassware surface. Thus, the analytes present in the water sample are quantitatively recovered into the extract. Using an SPE procedure for handling of such heterogeneous water samples usually requires filtration through a membrane filter prior to an extraction. Therefore, the result of such SPE analysis provides information only on the content of an analyte dissolved in the aqueous phase. Also, if no filtration was applied prior to SPE preconcentration, the analytes...
bound to suspended solids can hardly be trapped on the sorbent in the SPE cartridge and, therefore, they are lost for the analysis. The distribution of the analyte between the solid and aqueous phases depends on its hydrophobicity and its loss will increase with decreasing polarity.

### 3.2 Solid-phase Extraction

SPE, which has been developed intensively in recent decades, has become a powerful alternative technique to LLE owing to its simplicity, flexibility and high sample...
throughput. Additional advantages include reduction of toxic solvent consumption and greater health safety. An overview of the advantages of SPE over LLE in water analysis can be found in the literature.\textsuperscript{\textcopyright13–15,25} The results of experimental comparative tests have shown that a performance comparable to that of LLE could be achieved using SPE.\textsuperscript{26–31}

The basic principle of SPE is the transfer of analytes from the aqueous phase to the active sites of the adjacent solid phase. This transfer is stimulated by the selection of appropriate operational conditions in the system of three major components, water (liquid phase)–sorbent–analyte. After the replacement of the water by a suitable liquid phase in this system, the analyte can be desorbed from the sorbent and further analyzed. Usually, the SPE process is carried out in the column and is often referred to as low-performance liquid chromatography.

Many factors influence the efficiency of the SPE process, the two most important being capacity and retention. An insufficient capacity of the sorbent surface can cause its overloading and, consequently, earlier breakthrough of analytes. However, this situation is considered not to be very likely owing to the low concentrations of organic compounds in treated water samples and the relatively high sorption capacities of applied sorbents. The more critical factor is the retention of analytes, which should be a maximum in the water–sorbent–analyte system and a minimum in the eluent–sorbent–analyte system. The existence of these two contradictory demands on the strength of the sorbent–analyte interactions leads to the necessity to make a compromise during the selection of working conditions for sorption and desorption so as to obtain an optimum preconcentration.

A typical sequence of SPE includes the following steps: activation of the sorbent (wetting with a suitable solvent), conditioning (replacing of the activation solvent by the aqueous phase), percolation of the water sample, cleanup (removal of interfering components), drying of the sorbent bed, elution of accumulated analytes and regeneration of the sorbent [usually not recommended for disposable cartridges because of memory effects\textsuperscript{32} and/or hysteresis effects\textsuperscript{33}].

With respect to the system approach, two modes of SPE can be distinguished: off-line and on-line. In the online configuration, the SPE column output is connected directly to the analytical column, so that elution and separation of analytes are performed in one step. In the off-line configuration, the elution and separation of analytes are two separate steps. The chemistry and general principles are the same for both of these variants, but, the differences in their methodology are sometimes the reason for certain drawbacks or advantages of one or other of these approaches in a particular application.\textsuperscript{34}

3.2.1 Off-line Solid-phase Extraction

The off-line approach is very simple and even though it can be easily performed using a home-made system, a number of vacuum manifolds for sample extraction and analyte elution are commercially available. Similarly to traditional LLE, off-line SPE is also becoming a part of standardized protocols.\textsuperscript{35} In general, using an off-line configuration, high operational flexibility with regard to the selection of different materials and elution solvents is available. This approach allows the selective fractionation of the original sample and the simultaneous use of different separation and detection techniques for one sample extract. Asafu-Adjaye et al.\textsuperscript{36} separated kepone from other pesticides by flushing the loaded SPE column with hexane, which eluted DDT (1,1,1-trichloro-2,2-bis[p-chlorophenyl]-ethane), DDE (1,1-dichloro-2,2-bis[p-chlorophenyl]-ethylene) and HCB (hexachlorobenzene). Kepone and its metabolites were subsequently eluted with a mixture of hexane and diethyl ether. Wells et al.\textsuperscript{37} discussed SPE as the chromatographic technique to be used for the selective fractionation of wastewater effluents. An elution scheme incorporating water, methanol and methylene chloride for the fractionation of nonpolar organic toxicants using SPE was found to be effective for the separation and isolation of compounds with log $K_{ow}$ values ranging from 2.5 to 7 from aqueous solutions and for toxicants from a sediment pore water sample.\textsuperscript{38}

In addition to the fractionation possibility, off-line SPE is a good substitute for LLE in the preconcentration of pesticides with a large range of polarity. The efficiency of the preconcentration depends substantially on the selection of a suitable solid phase. Bonded silicas, polymers and carbon sorbents are the most frequently applied SPE materials in newly developed sample-handling procedures used for the determination of pesticides in water.\textsuperscript{39,40} When needed, the combination of several SPE columns and the use of several eluting solvents can increase the efficiency of the SPE procedure. DiCorcia et al.\textsuperscript{41} extracted phenoxyacetic acid herbicides from water using a miniaturized cartridge containing GCB in the top part and a silica-based strong anion exchanger in the bottom part. After the percolation of the water sample through this cartridge, the anion exchanger was activated with sodium acetate solution. The sorbed analytes were then transferred from the GCB to the anion exchanger with methylene chloride–methanol solvent mixture basified with sodium hydroxide. After washing, herbicides were desorbed from the anion exchanger with water–methanol containing trifluoroacetic acid and
potassium chloride. The DLs were in the parts per trillion (nanograms per liter) range. The use of off-line SPE in screening for pesticides in water requires simple instrumentation and provides low DLs owing to the possibility of partial evaporation of the eluate from the SPE cartridge. DiCorcia et al.\(^4\) presented an off-line approach to monitoring a large group of pesticides in ground- and river water. The method incorporated a fractionation of analytes into basic and neutral compounds and acidic compounds, based on two different interaction mechanisms of GCB. Processing of large volumes of water (0.5–2 L) and evaporation of the eluates led to DLs lower than 0.1 \(\mu g\) L\(^{-1}\) for most of the pesticides in this case.

The ease of manipulation with disposable SPE media is being further enhanced. In the 1990s, membrane extraction disks were introduced as an attractive kind of SPE material. These membranes consist of a fibrillated polytetrafluoroethylene (PTFE) matrix in which sorbents such as bonded silicas, polymers or ion exchangers are enmeshed. Owing to the internal structure of the disks, high flow rates of water sample can be achieved and a reduction of the recovery due to channelling is avoided. The easy manipulation with disks makes them suitable for quick testing methods. Owing to obvious benefits of their use, disks became the preferred media for Drinking Water Test Methods as defined by the USEPA.\(^4\)^\(^3\) In the determination of pesticides in water, the eluate from the disk can be injected into a GC system and, if necessary, derivatization of analytes can be performed prior to the injection.\(^4\)\(^4\) For screening of a wide range of pesticides, the eluate can be analyzed by both GC and liquid chromatography (LC) systems simultaneously.\(^4\)\(^5\)

### 3.2.2 On-line Solid-phase Extraction

The principle of the on-line approach is the direct transfer of adsorbed analytes from the SPE column to the analytical column by the mobile phase. Hence this approach is also called precolumn switching or precolumn technology. The principles and technical aspects of the on-line approach, especially for HPLC analyses, have been described thoroughly\(^1\)\(^3\),\(^3\)\(^4\)\(^6\) and many applications have been published in environmental and in biomedical analysis.

A typical simple on-line system is shown in Figure 2. It consists of two circuits connected together by the switching valve. The aqueous sample is introduced to the precolumn by the pump in the low-pressure (preconcentration) circuit and, subsequently, the precolumn is switched to the high-pressure circuit where the analytes are eluted by the mobile phase directly into the analytical column. The sample volume applied usually ranges from 10 to 200 mL depending on the analytes and on the total organic load of the water sample. The internal volume of the precolumn ranges from several tens to several hundreds of microliters. In principle, sorbent material in the SPE precolumn should be identical with the packing material in the analytical column to prevent broadening of chromatographic peaks (band broadening). Therefore, owing to the prevalence of octadecysilica LC columns, C\(_{18}\) is frequently used as a precolumn packing. C\(_{18}\) precolumns are sufficient for the preconcentration of compounds with low polarity but problems occur in case of polar analytes. In such case, a sorbent having stronger interactions with these analytes than a conventional C\(_{18}\) material should be used in the precolumn. If the precolumn containing more hydrophobic material is connected to a C\(_{18}\) analytical column, this will lead to additional band broadening. Hence, a compromise between sufficient retention in the precolumn and band broadening in the analytical column is needed. Styrene–divinylbenzene polymeric sorbent was found to be a good solution to this problem.\(^4\)\(^7\)–\(^5\)\(^1\) The particle size of the precolumn material should be the same as used in the analytical column; however, it is possible to use particles with a larger diameter when processing water samples with a high concentration of suspended solids to prevent problems with high back-pressure.

The need for continuous monitoring of water quality initiated the development of rapid screening on-line SPE/HPLC methods with diode-array ultraviolet detection (DAD/UV). The use of on-line systems for this purpose allowed rapid access to information on water quality and a relatively high frequency of sampling. Within the framework of an international Rhine Basin Program, an on-line SPE/LC/DAD/UV system capable of screening for a large range of pesticides with different polarities was tested for more than 50 pesticides\(^4\)\(^8\) and then was fully automated and validated for the determination of 27 pesticides.\(^5\)\(^1\) Similar on-line systems for broad-range determinations of pesticides in water were developed using membrane extraction disks as packing

of the precolumn. An interesting option in this kind of application is the use of a bifunctional membrane extraction disk cartridge containing both C18 and cation-exchange disks. The combination of SPE materials having different functionalities allowed the simultaneous determination of basic, neutral and acidic pesticides. On-line systems can be used also for preconcentration of more "problematic" compounds. To improve the preconcentration efficiency for pyrethroid insecticides having both hydrophobic and hydrophilic behavior, both breakthrough on the precolumn and adsorption on the inner walls and surfaces were prevented by adding a neutral surfactant to the aqueous sample. The developed method involving micelle-mediated preconcentration was tested for surface water analysis and the whole system was found to be robust and to give good and repeatable results.

To increase the functionality of the on-line SPE system, a more sophisticated scheme than that displayed in Figure 2 can be designed. For the preconcentration and fractionation of organic pollutants in industrial effluents, Nielen et al. used three precolumns in series (C18, PRP-1 and a cation exchanger) and eluted all precolumns separately. Brouwer et al. connected two polymer (PLRP-S) precolumns in series and the outlet of each precolumn was directed on-line to a separate PLRP-S analytical column. While the first precolumn was operated in the reversed-phase mode, trace enrichment in the second precolumn was based on an ion-pairing mechanism. This allowed the preconcentration of acidic and basic compounds within one analysis. The same authors developed a similar system with one HPLC analytical column. In this system, they used as precolumns specially designed holders packed with membrane extraction disks. A top state-of-the-art level in the development of sophisticated on-line systems was achieved by Slobodnik et al., who developed an integrated system combining on-line SPE with LC and GC separation and detection by mass spectrometry (MS). The trace enrichment procedure was automated by a Prospekt cartridge-exchange/solvent-selection/valve-switching unit. After loading of the water sample, the precolumn was eluted on-line in two subsequent runs, first on to the gas chromatography/mass spectrometry (GC/MS) system and, next, onto the LC/DAD/UV/MS system using a particle beam interface (Figure 3). With this system, GC/MS, LC/DAD/UV and liquid chromatography/mass spectrometry (LC/MS) data on the same water sample could be obtained within 3 h, providing a large amount of structural information on unknown organic compounds present in the sample.

On-line coupling of SPE to GC is more complicated than to HPLC owing to problems with the liquid-phase/gas-phase interface. Even though this approach was already applied to the determination of pesticides in water in the 1980s, more frequent use of on-line SPE/GC can be observed in the 1990s. An automatic SPE sample

preparation system was coupled on-line to capillary GC/ECD by means of a loop-type interface equipped with a solvent vapor exit. Using SPE cartridges packed with silica for cleanup of the hexane extract of a water sample, it was possible to analyze concentrated surface water extracts for a group of organochlorine and pyrethroid insecticides present in the water at parts per trillion levels. This approach can be considered as a combination of LLE and SPE. If, in an SPE/GC system, the SPE cartridge is used for the direct accumulation of analytes from water, drying of the eluent prior to its injection into the GC system is desirable. For this purpose a small cartridge containing a suitable drying agent can be inserted between the SPE column and the GC system. Introduction of programmable temperature vaporization (PTV) injectors in GC permitted the use of a GC liner packed with a solid support as an alternative to a SPE column. Thus, large volumes of water samples (up to 1 mL) can be introduced into a GC injector, water is separated in the liner and, after switching of a valve, compounds are thermally desorbed in the splitless mode by heating the PTV unit into the GC column. The DLs obtained with such systems are in the sub-parts per billion range.

The application of a sophisticated cleanup procedure is not the only possibility for achieving a high selectivity. An alternative way is the use of a highly selective solid phase such as ion exchangers, metal-loaded sorbents or immunosorbents. The procedures utilizing these materials are rather complicated and require a skilled operator, but their efficiency and suitability for special target analyses have been demonstrated by different authors. A new development in the use of a solid phase for the preconcentration of pesticides from water is SPME, introduced and thoroughly developed by Pawliszyn et al. SPME is based on a fiber coated with the stationary phase (e.g. polysiloxane or polyacrylate polymers) that is used for the direct extraction of organic compounds from water by dipping the fiber into the water sample. After sorption, the fiber is transferred into the heated injector of a gas chromatograph where the organic compounds are thermally desorbed from the stationary phase. This technique is becoming popular, as it is fast, sensitive, inexpensive, portable and solvent-free. Numerous applications of SPME in water analysis were reviewed by Eisert and Levsen and SPME was found to be very attractive for routine use even though it still represents an exciting field of research.

### 3.3 Other Sample-handling Methods

Apart from LLE and SPE, only a few techniques based mostly on membrane and electromigration processes have received the attention of environmental analysts for handling of aqueous samples.

A supported liquid membrane (SLM) is typically constructed by immobilizing an immiscible liquid within the pores of a microporous film. In principle, the immobilized liquid can be aqueous or organic and various materials such as PTFE, cellulose acetate and polypropylene can be used as a support. The sample preparation set-up can be coupled on-line to the chromatograph. The use of closed systems minimizes the risk of contamination and losses during sample-handling. Since the volumes of organic solvent used in such a system are very small (<500 μL) and the same solvent volume is used for a large number of samples, it is possible to use solvents which are expensive and also considered hazardous in batch extractions. Dihexyl ether was used in a liquid membrane applied for sample preparation for the determination of sulfonylurea herbicides in aqueous samples. The technique studied in this work utilized extraction and back-extraction in an automated flow system and was coupled on-line to an LC system. The extractor unit consisted of an immobilized liquid membrane, separating two aqueous phases. From the acidified donor phase the analytes were extracted into the organic solvent of the membrane. After traversing the membrane, they were back-extracted into an alkaline/neutral aqueous acceptor phase. The use of the precolumn technique made it possible to inject the total amount of the extracted analytes. A liquid membrane device was also used for continuous sampling from a water stream in an integrated field sampling method for MCPA. MCPA was transferred as an uncharged species from a donor phase to a stagnant acceptor phase where it was trapped in a buffer, permitting a high degree of enrichment. The final determination was made by HPLC utilizing a precolumn instead of a sample loop in the injector. The method has been found to give values in good agreement with a technique based on batch extraction and GC with a DL of ca. 0.03 ppb.

Membrane-based techniques can be efficient not only for trace enrichment purposes but also for the removal of interferences. The potential of the on-line combination of dialysis for the removal of interfering humic substances from environmental samples and trace enrichment on a precolumn packed with C_{18} for the determination of polar pesticides by column LC with UV detection was investigated by van de Merbel et al. using six phenylurea herbicides as model compounds. Using a planar dialysis membrane with a molecular weight cut-off value of 3.5 kDa and a sample of 1.2 mL, interfering humic substances were sufficiently removed to allow the automated determination of selected phenylureas at the 1 ppb level. The transport of ionizable compounds through membranes can be supported by application of a voltage. Basic considerations for analyte compounds through membranes can be supported by application of a voltage. Basic considerations for analyte compounds through membranes can be supported by application of a voltage.
method were presented by Debets et al.\textsuperscript{(72)} A practical application of on-line electrodialysis for the treatment of natural waters prior to the column LC determination of polar pollutants was described by Groenewegen et al.\textsuperscript{(73)} Another approach to sample-handling of water samples containing ionizable compounds is the use of electromigration techniques. On-line coupling of isotachophoretic pretreatment to capillary zone electrophoresis (CZE) allowed the determination of paraquat and diquat at nanomoles per liter levels in tap and surface water.\textsuperscript{(74)} Isotachophoresis was also presented as a selective sample pretreatment technique for ionic substances prior to HPLC analysis.\textsuperscript{(75)}

Supercritical fluid extraction (SFE) has been demonstrated to be a good method for preparation of solid samples. However, there is only a very limited number of papers dealing with direct SFE of aqueous samples and owing to experimental problems this approach does not seem very promising for the future.\textsuperscript{(76)}

4 CONCLUSIONS

Sample preparation, for reasons mentioned in the Introduction, will remain a fertile area of development in the future. Reduction of time and costs needed for sample handling and reduction of the consumption of toxic solvents will be the leading factors supporting any progress in this area. Automation will save time and reduce errors. New approaches and new techniques will make sample handling safer and more effective. There will be the simultaneous development of both simple and fast preconcentration schemes for routine use in rapid standard methods and sophisticated procedures coping with the continuous development of modern polar pesticides. The growing interest in ecotoxicological assessment and biomonitoring will influence the prevailing “chemical” character of the preparation of water samples. Also, obviously, research in environmental pesticide analysis will be tightly bound to regulatory policies in environmental protection and any pushing of regulatory levels to lower values or introduction of new parameters to the “Black Lists” will further stimulate the development of sample-handling techniques, especially for polar hydrophilic analytes.

Owing to their widespread use in agriculture and urban weed control and because of their high mobility in the subsoil, polar pesticides such as phenoxy acids and other acidic pesticides have been especially considered as a potential source of groundwater contamination. In Europe, pesticide residues tolerances in drinking water were set by the European Union Commission to 100 ng L\(^{-1}\) for an individual compound and 500 ng L\(^{-1}\) for the sum of pesticide residues. These maximum tolerances constitute a real challenge to analysts working in the field of pesticide residue monitoring. In the following article, analytical methods for the multiresidue analysis of phenoxy acids and other acidic pesticides in environmental samples at trace level concentrations are presented. Analytical methods using capillary gas chromatography (GC), high-performance liquid chromatography (HPLC), capillary zone electrophoresis (CZE) and automated multiple development thin-layer chromatography (AMDTLC) are described. GC methods are most often used in routine analysis of acidic pesticides owing to their unrivaled advantages in separation power. GC methods can be used in multiresidue analysis of up to more than 50 analytes at trace level concentrations. Owing to their high polarity and low volatility, acidic pesticides are not directly amenable to GC analysis, thus suitable derivatization methods are required. The applicability and drawbacks of several derivatization methods are described in detail. GC can be used with various detection methods such as electron capture detection (ECD), nitrogen–phosphorus detection (NPD), atomic emission detection (AED) or mass spectrometry (MS). GC/MS (gas chromatography/mass spectrometry) or GC/MS/MS (tandem mass spectrometry) detection provides the highest possible level of confidence independent of the complexity of the environmental matrix from water or even soil samples. The highest selectivity and sensitivity is achieved in selected ion monitoring (SIM) or in selected reaction monitoring (SRM) mode. Progress in coupling of HPLC to MS has improved the possibilities of identification and confirmation of analytes at trace level concentrations using HPLC methods and new promising analytical approaches such as HPLC coupled to atmospheric pressure ionization (API) MS/MS will gain much importance in the future. Enantioselective separation of different chiral isomers of phenoxy acid pesticides can be achieved applying CZE or by applying GC or HPLC with special chiral phases.

In water analysis, conventional liquid–liquid extraction (LLE) has mostly been replaced by solid-phase extraction (SPE) methods to extract and enrich the analytes from the samples. Two standard operating procedures (SOPs) are presented as examples for the analysis of phenoxy acids and other acidic pesticides in environmental samples (water and soil). Detection limits down to the low nanogram per liter level or down to the low microgram per kilogram level can be achieved for water samples or soil samples, respectively. Several examples for the environmental analysis of actual samples show the performance and sensitivity of today’s trace level multiresidue analysis.

1 INTRODUCTION

The occurrence of polar pesticides in the environment has become a subject of increased public concern. Owing to their widespread use in agriculture and urban weed control and because of their high mobility in the subsoil, polar pesticides such as phenoxy acids and other acidic pesticides have been especially considered as a potential source of groundwater contamination. Consequently, in many environmental investigations these pesticides are analyzed to check their concentration against the maximum tolerances of pesticide residues in drinking water.

In Europe, these tolerances were set by the European Union Commission\(^{[1]}\) to 100 ng L\(^{-1}\) for an individual compound and 500 ng L\(^{-1}\) for the sum of pesticide...
PESTICIDES residues. These maximum tolerances constitute a real challenge to analysts working in the field of pesticide residue monitoring. Analytical routine methods have to guarantee high accuracy and reliability at trace level concentrations independent of the amount and composition of the environmental matrix. Because of their polar structures, extraction from environmental samples and their analysis are much more difficult for acidic pesticides than for nonpolar pesticides such as organochlorine or triazine pesticides such as DDT (2,2'-bis(chlorophenyl)-1,1,1-trichloroethane) or atrazine. To lower the costs of routine analysis it is also desirable to determine as many analytes as possible at one time in one procedure applying only a few so-called multimethods.

In this article, analytical procedures are presented which fulfill all stated requirements enabling multiresidue analysis of up to 40 acidic pesticides at trace level concentrations in water or soil.

2 AGRICULTURAL USE AND IMPORTANCE

Phenoxy acid pesticides, also called phenoxy alkanoic acid pesticides, are selective herbicides developed in the 1940s in the course of attempts to synthesize analogs of the auxin, $\beta$-indoleacetic acid, which had been recognized as a natural plant growth regulator. The common mode of action of auxin-type herbicides is to mimic natural auxin, $\beta$-indoleacetic acid, thereby producing an abnormal lethal growth. On the molecular scale, they influence the levels of RNA and DNA polymerase and enzymes that regulate

normal growth and development processes.\(^2\) Although phenoxy acids are the oldest group among the synthetic herbicides\(^3\) they are still frequently used worldwide. In Germany, the phenoxy acids dichlorprop (4), mecoprop (8), 2,4-D ((2,4-dichlorophenoxy)acetic acid) (2) and MCPA ((4-chloro-2-methylphenoxy)acetic acid) (6) are among the most important agricultural pesticides.\(^4\) In total, more than 1000 tonnes of phenoxy acid herbicides are applied annually in Germany.\(^4\) Additionally, new polar herbicides have been developed and introduced in agriculture.

Some acidic pesticides can be determined in routine multimethods together with the phenoxy acids. The common names of all pesticides that can be analyzed with the analytical methods presented in this article are compiled in Table 1 together with their IUPAC (International Union of Pure and Applied Chemistry) names, CAS (Chemical Abstracts Service) numbers and their mode of action as pesticides. The structural formulae of all compounds are shown; (1) to (9) are phenoxyalkanoic acid herbicides, (10) to (19) are amide and phenolic pesticides and (20) to (40) are other acidic pesticides. The range of analytes includes many carboxylic acids and also two amides, namely bentazone (10) and fuberidazole (11), and some phenolic pesticides such as bromoxynil (13) and ioxynil (14) which are frequently used in combination with phenoxy acid herbicides to broaden the range of weeds controlled.\(^5\) As a whole, more than 40 acidic pesticides can be analyzed from all different kinds of water and soil samples using the methods described in this article.

### 3 INSTRUMENTAL ANALYSIS

Separation of the analytes from each other and from interfering matrix compounds is a prerequisite in environmental multiresidue analysis. Therefore, HPLC and capillary GC are the two favorite separation techniques in multiresidue analysis of acidic herbicides in water or soil samples. As will be discussed in detail in the following sections, both techniques have advantages and drawbacks when analyzing acidic pesticides. At the moment, GC methods in combination with MS have some advantages compared to HPLC or other GC methods and thus they are most frequently applied in all modern environmental laboratories. Nevertheless, there are some very promising new instruments, such as HPLC coupled to API/MS/MS. As prices for these sophisticated but still easy to use instruments are decreasing they will probably gain much more importance in environmental analysis of polar pesticides. Apart from GC and HPLC methods there are also other techniques which are used for the analysis of acidic pesticides. A modern variation of thin-layer chromatography (TLC) is the so-called AMDTLC which offers much higher separation power than conventional TLC methods. In combination with HPLC the separation power of both techniques can be enhanced remarkably,\(^6\) but has not yet been applied to acidic pesticides. Methods applying CZE have some importance, especially when information about the distribution of different enantiomers of acidic pesticides in the environment is required. There are also some immunochemical methods which have been developed for the analysis of different phenoxy acid herbicides, such as 2,4-D (2), 2,4,5-T (9), mecoprop (8) and dichlorprop (4).\(^7\)–\(^20\) Owing to their selectivity, the immunochemical assays are only suitable for single compound analysis. These methods often show some cross reactivities to chemically related compounds whenever these occur at higher concentrations in the samples. The cross reactivities are, however, not normally desirable and have to be suppressed to avoid false positive results. Thus, immunochemical methods may be used as rapid screening methods in environmental analysis but have not been included in this article describing multiresidue methods.

#### 3.1 Capillary Gas Chromatography

Capillary GC is the analytical method with the greatest separation power and therefore the best suited to multiresidue analysis of pesticides from environmental samples. Automated GC analysis has become routine for environmental samples, with autosamplers carrying out automatic injection. There are many monographs about GC and GC/MS which describe the hardware, the techniques, potential interferences and applications in environmental analysis.\(^21\)–\(^29\) A major drawback of conventional GC analysis using hot split/splitless injection is that only small proportions of the samples (1–5 µL) can be introduced into the GC. Therefore, new large volume injection techniques have been developed\(^30\)–\(^32\) to enable the direct analysis of up to 1 mL of sample extracts to improve, if necessary, the detection limits of GC analysis. One technique, the programmed temperature vaporization (PTV) has been used for the analysis of acidic pesticides, as will be described in section 3.1.4.2.

The ease of coupling GC to highly sensitive detectors such as the ECD, the NPD or the flame photometric detector (FPD), and most importantly the subsequent coupling of GC to MS, further increased the prevalence of GC over other analytical techniques in trace level analysis of pesticides.\(^33\) As will be described in sections 3.1.3.2, 3.1.3.3 and 3.1.3.4, the use of MS applying special acquisition and/or ionization techniques such as SIM, chemical ionization (CI) or MS/MS acquisition enables the analysis of pesticide residues at parts per billion (ppb)
or even parts per trillion (ppt) levels. GC/MS detection also provides the highest possible level of confidence independent of the complexity of the matrix from water or even soil samples. Another new and very interesting GC detector is the AED, which enables the element specific analysis of pesticide residues. Its performance in the determination of acidic pesticides will be described in section 3.1.4.2.

Because of their high polarity and low volatility, acidic pesticides are not directly amenable to GC analysis and have to be derivatized using suitable derivatizing agents. Many different derivatization methods have been described and will be discussed in the following section. The determination of these derivatives applying GC with ECD, NPD, AED or MS detection will be demonstrated in sections 3.1.2 to 3.1.4.

3.1.1 Derivatization Techniques

Methylation by diazomethane and derivatization using pentafluorobenzyl bromide (PFBBBr) are most commonly used for the determination of phenoxy acids and other acidic pesticides by GC. Depending upon the individual analytical problem there are some other very interesting alternative derivatization techniques whose benefits, drawbacks and suitability for the different compound classes will be described in this section.

3.1.1.1 Alkylation to Methyl, Ethyl and Butyl Esters

Methylation of phenoxy acid herbicides with methanol/sulfuric acid is one of the classical and very reliable derivatization methods. Unfortunately, methylation of phenolic or amide pesticides is not possible using this procedure. Therefore, it has for the most part been substituted by diazomethane derivatization which is also able to methylate compounds such as bromoxynil, ioxynil or bentazone which are often integrated in multiple-residue methods in water analysis. Caution: Diazomethane has to be handled carefully, because it is toxic and known to be a potent carcinogen and mutagen. Diazomethane may also explode when used inappropriately, especially at higher concentrations. Recently, Rimmer et al. described the analysis of six phenoxy acid herbicides using trimethylsilyldiazomethane, which is commercially available. Derivatization with trimethylsilyldiazomethane provides a less hazardous method for preparing the phenoxy acid methyl esters under milder conditions than with diazomethane.

As long as only carboxylic pesticides are to be analyzed, alkylation with chloroformates is an interesting alternative. Using commercially available methyl, ethyl or butyl chloroformates, it is very easy to produce the corresponding methyl, ethyl or butyl esters. It is thus possible to identify and confirm acidic pesticides using only one GC column and a conventional ECD as shown in section 3.1.2. Methyl esters may also be formed by derivatization with boron trifluoride–methanol or methyl iodide. Another interesting technique for the methylation of acidic pesticides is the intra-injector derivatization using trimethylsilylhydroxide (TMSH) or trimethylammonium hydroxide (TMAH). These derivatizations proceed very quickly and easily, but may be problematic in quantification, especially when interfering matrix compounds are involved.

There is one common drawback with all the above alkyl derivatives: they show some problems in ECD detection of lower chlorinated analytes such as mecoprop, MCPA or MCPB. Other acidic pesticides such as bentazone or 2-(1-naphthyl)acetic acid are not detected by the ECD at all. Thus, many recent methods recommend GC/MS detection for the analysis of the methyl derivatives. Some typical alkylation procedures are described in detail in the following sections.

Methylation with Methanol/Sulfuric Acid. This derivatization procedure is according to the German standard method. An aliquot of a standard solution or sample extract dissolved in methanol (about 2 mL) is combined with 1 mL of sulfuric acid (\(\rho\left(\text{H}_2\text{SO}_4\right) = 1.84\ \text{g L}^{-1}\)) in a 10-mL volumetric flask. The reaction mixture is allowed to stand for 10 min. Then the volume is adjusted to 10 mL by adding distilled water. One milliliter of hexane is added to the mixture which is then vigorously shaken. A portion of 1–2 \(\mu\)L of the hexane layer is injected into the GC.

For suitable GC conditions see sections on Methylation with Diazomethane and Alkylation using Chloroformates below.

Methylation with Diazomethane. This derivatization procedure is according to the EPA (Environmental Protection Agency) and the German standard method. A diazomethane solution in methyl tert-butyl ether (MTBE) is produced by using a diazomethane solution generator under a fume hood as reported in detail elsewhere. (Caution: Wear appropriate safety equipment to minimize skin contact and inhalation hazards. Avoid heat, because diazomethane is explosive near 90°C.) Before use, the diazomethane solution can be stored for a few days or weeks at 0–5°C or –18°C.

An aliquot of a standard solution or sample extract containing the acidic pesticides (e.g. 1 mL) is dried under a gentle stream of nitrogen in a reaction tube. A portion of 0.5 mL of the diazomethane solution is added to the extract. After addition of diazomethane solution the analyte extracts should turn and remain yellow for more than 2 min, otherwise the methylation procedure should be repeated. The reaction tubes are then sealed with stoppers and held at room temperature for 30 min under a fume hood. The unreacted diazomethane is destroyed by adding 0.1–0.2-g of silicic acid or by evaporation to
a defined volume >200µL. The reaction tubes are then left to stand for approximately 20 min until evolution of nitrogen gas ceases. The extracts are adjusted to a defined volume by adding MTBE and injected (2 µL) directly or after a cleanup procedure using Florisil\(^{47}\) into GC.

Suitable GC conditions\(^{37,45}\) are as follows. Instrument: GC/ECD or GC/MS. Capillary column: HT-5 (SE-54) fused-silica capillary column, 25 m × 0.25 mm ID (inner dimensions), with a film thickness of 0.1µm and hot splitless injection. Carrier gas: helium (0.8 bar). The oven temperature is held at 80°C for 2 min following injection, then programmed at 20°C min\(^{-1}\) to 160°C, which is held for 4 min, then increased at 4°C min\(^{-1}\) to 200°C, followed by an increase of 25°C min\(^{-1}\) to 260°C and finally held for 3 min. Injection port, detector (ECD) or interface (MS) temperatures are set to 250°C, 300°C and 270°C, respectively.

**Alkylation using Chloroformates.** This derivatization procedure is according to Butz and Stan.\(^{53}\) An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a reaction tube. To obtain the ethyl esters the dried residue is dissolved in 100µL of a reaction mixture containing acetonitrile, ethanol, water and pyridine (5:2:2:1 v/v) followed by 7µL of ethyl chloroformate. To obtain the methyl esters the dried residue is dissolved in 100µL of a reaction mixture containing acetonitrile, methanol, water and pyridine (2:2:7:1 v/v) followed by 7µL of methyl chloroformate. To obtain the butyl esters the dried residue is dissolved in 100µL of a reaction mixture containing acetonitrile, butanol, water and pyridine (2:2:6:1 v/v) followed by 7µL of butyl chloroformate. Then the reaction tube is shaken gently against a pad for about 5 s to initiate the gas evolution. The solution is dried under a gentle stream of nitrogen and the residue is dissolved in 100µL of toluene. A 1-µL portion of this solution is injected into the GC.

Suitable GC conditions\(^{37}\) are as follows. Instrument: GC/ECD or GC/MS. Capillary column: HP-5 fused-silica capillary column, 25 m × 0.2 mm ID, with a film thickness of 0.32µm and hot splitless injection with the split closed for 1 min. Carrier gas: helium. The oven temperature is held at 100°C for 1 min following injection, then programmed at 30°C min\(^{-1}\) to 150°C, which is held for 2 min, then increased at 3°C min\(^{-1}\) to 205°C, followed by an increase of 10°C min\(^{-1}\) to 260°C and finally held for 25 min. Injection port, detector (ECD) or interface (MS) temperatures are set to 220°C, 300°C and 190°C, respectively.

**3.1.1.2 Alkylation Introducing Hetero Atoms** Derivatization methods to form alkyl esters containing hetero atoms such as fluorine or chlorine have been developed to overcome the sensitivity problem of the ECD. Some of the resulting derivatives also have excellent mass spectrometric properties for trace level multiresidue analysis applying GC/MS with SIM programming (see section 3.1.3.2).

The formation of 2,2,2-trifluoroethyl,\(^{61–63}\) 2-chloroethyl,\(^{61}\) 2,2,2-trichloroethyl\(^{61,64}\) and 2,2,3,3,3-pentafluoropropyl esters\(^{64}\) of phenoxy acids has been described. In environmental analysis the formation of pentafluorobenzyl (PFB) esters by reaction with PFBBr has gained much importance.\(^{28,64–79}\) PFBB esters increase the sensitivity of ECD detection tremendously and they allow the determination of acidic pesticides independent of their substitution with chlorine. Derivatization with PFBBBr enables the determination of phenoxy acid herbicides, other carboxylic acid pesticides, some phenolic pesticides and even amide pesticides such as bentazone or fuberidazole,\(^{28,75,76}\)

Three different procedures for the formation of PFBB esters have been reported. The classical procedure is performed using acetonitrile as solvent and potassium carbonate as catalyst.\(^{64–71,78}\) Heberer et al.\(^{28,75,76}\) described an alternative procedure using toluene as solvent and triethylamine as basic catalyst. This procedure has some advantages when analyzing environmental samples because many interfering matrix compounds are excluded from GC before analysis.\(^{28,76}\) Meiring et al.\(^{73}\) described the phase-transfer-catalyzed derivatization of polar pesticides using tetrahexylammonium hydrogensulphate as complexing agent which transports the analytes from the aqueous layer into a dichloromethane layer where they are derivatized with PFBBBr.

As shown in section 3.1.2, a major drawback of the PFB ester procedure is the large number of interfering substances in the extract from the environmental matrix when the extract is analyzed by GC/ECD.\(^{28,64,75}\) The analysis of derivatized sample extracts by GC/ECD often requires time-consuming cleanup procedures.\(^{64}\) Thus, the screening of these derivatives using GC/MS with SIM (see section 3.1.3.2) or using GC with AED, as shown in section 3.1.4.2, has great advantages compared to conventional GC/ECD methods. GC/MS with SIM enables the analysis of more than 40 acidic pesticides down to the low microgram or even nanogram per kilogram level in soil samples and down to the low nanogram per liter level in water samples, as will be shown in section 4.

**Pentafluorobenzylolation.** A first derivatization procedure is according to Heberer et al.\(^{28,75,76}\) An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a sample vial. A 200-µL portion of a PFBBBr solution (100-µL PFBBr dissolved in 4.9-mL toluene) and 2-µL triethylamine are added to the residue. The vial is capped with a Teflon\(^{®}\)-lined septum and the reaction mixture is heated for 1 h at 110°C
simply by placing in a drying cabinet. The mixture is then cooled to room temperature, the vials are decapped and the solution containing the derivatized compounds is dried under a gentle stream of nitrogen. The residue is dissolved in 100 µL of toluene and 2 µL of this solution is injected into the GC/MS.

The second derivatization procedure is according to Gurka et al.(65) An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a sample tube. Four milliliters acetone, 30 µL of 10% K$_2$CO$_3$ in distilled water and 200 µL of 3% PFBBr in acetone are added to the residue. The tube is closed with a glass stopper and mixed on a vortex mixer. The tube is then heated for 3 h at 60 °C in a tube heater. The mixture is evaporated to 0.5 mL under a gentle stream of nitrogen. A 2-µL portion of hexane is added to the solution and evaporation is repeated to dryness at room temperature. The residue is dissolved in toluene–hexane (1:6) for column cleanup using silica columns topped with anhydrous Na$_2$SO$_4$. The column is prewetted with 5-mL hexane (let drain to top of sorbent) and the reaction mixture is transferred quantitatively to the top of the column. The column is then washed with 8 mL of toluene–hexane mixture (1:6) and the PFB derivatives are eluted with toluene–hexane (9:1) to collect 8.0 mL. An aliquot of this fraction is analyzed by GC/ECD or GC/MS.

Suitable GC conditions(28,75,76) are as follows. Instrument: GC/ECD, GC/AED or GC/MS. Capillary column: 25 m × 0.2 mm ID × 0.33 µm HP-5 capillary column fitted with a 1.5 m × 0.32 mm ID × 0.33 µm HP-5 precolumn. Carrier gas is helium (purity: 99.999%) set to a flow of 28 cm s$^{-1}$ at the initial temperature. The oven temperature is held at 100 °C for 1 min following injection, then programmed at 30 °C min$^{-1}$ to 150 °C, which is held for 1 min, then at 3 °C min$^{-1}$ to 205 °C followed by 10 °C min$^{-1}$ to 260 °C and finally held for 23 min. Injection port, detector (ECD) or interface (MS) temperatures are set to 230 °C, 300 °C and 250 °C, respectively. Samples are injected using hot splitless injection with the split closed for 0.9 min.

Trifluoroethylolation. This derivatization procedure is according to Lee et al.(63) An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a Teflon$^\circledR$-capped vial. A 0.5-mL portion of sulfuric acid (analytical grade) and 1.0 mL of 2,2,2-trifluoroethanol are added to the vial. The vial is capped tightly, the mixture is gently swirled. The reaction is carried out in a water bath at 90 °C for 4 h. Then the vial is cooled down under flowing tap water. Deionized water (6 mL) and 2 mL of hexane are added to the vial which is then shaken vigorously. After separation of the two liquid phases, 1 mL of the hexane layer is transferred to a 10-mL volumetric flask and diluted to volume with hexane. A 2-µL portion of this solution is injected into the GC.

Suitable GC conditions(63) are as follows.

1. Instrument: GC/ECD. Capillary column: Rtx-35 fused-silica capillary column, 30 m × 0.53 mm ID, with a film thickness of 0.5 µm. Samples are injected using splitless injection. Carrier gas is helium, make-up gas 5% methane in argon. The oven temperature is held at 130 °C for 6 min following injection, then programmed at 30 °C min$^{-1}$ to 160 °C, which is held for 5 min, then increased to 210 °C, which is held for 6 min followed by an increase to 260 °C and finally held for 3 min. Injection port and detector temperatures are set to 265 °C and 300 °C respectively.

2. Instrument: GC/MS. Capillary column: HP-5 fused-silica capillary column, 30 m × 0.25 mm ID, with a film thickness of 0.25 µm and splitless injection. Carrier gas is helium set to a head pressure of 90 kPa. The oven temperature is held at 80 °C for 3 min following injection, then programmed at 30 °C min$^{-1}$ to 140 °C, which is held for 8 min, then increased to 210 °C, which is held for 5 min followed by an increase to 260 °C and finally held for 5 min. Injection port and interface temperatures are set to 230 °C and 280 °C respectively.

3.1.1.3 Silylation Silylation is probably the most versatile derivatization technique currently available to enhance GC performance by blocking protic sites.(80) Therefore, it is frequently used especially in clinical chemistry. The use of silylation reagents has, however, one major drawback; almost all of the reagents and the resulting derivatives are sensitive to the hydrolytic effects of moisture. Thus, for a long time silylation with (2-cyanoethyl)dimethyl(diethyly amino) silane (CEDMSDEA) was the only described silylation procedure for the analysis of acidic pesticides.(81,82)

Another promising method is the derivatization of acidic pesticides with N-(tert-butyldimethylsilyl)-N-methyltrifluoroacetamide (MTBSTFA) forming their tert-butyldimethylsilyl (TBDMS) derivatives. The derivatization procedure is simple and rapid and, as shown in section 3.1.3.1, the resulting TBDMS derivatives exhibit characteristic EI (electron ionization) MS spectra. In contrast to other silylated derivatives they have proven to be stable for several days, even in the presence of moisture. The remarkable stability of the derivatives to hydrolysis can be explained by the sterical hindrance caused by the large tertiary butyl moiety which protects the silicon–oxygen bond from hydrolytic attack.(83) This method was successfully applied by Heberer and Stan(83) for the analysis of more than 50 substituted phenols including also six phenolic pesticides in water analysis. As presented here, this derivatization technique is also suitable
for the determination of other acidic pesticides, including all pesticides containing carboxylic acids. Unfortunately, amides such as bentazone (10) or fuberidazole (11) are not derivatized by this method.

**Silylation with (2-Cyanoethyl)dimethyl(diethylamino)-silane.** This derivatization procedure is according to Bertrand et al.\(^{(31)}\) The preparation of the silylating reagent CEDMSDEA was published in 1986 by Bertrand et al.\(^{(31)}\) A 20-µL portion of a standard solution or a sample extract in ethyl acetate is put into a 0.5-mL Reacti-Vial pretreated with dichlorodimethylsilane for reproducibility. Then 60 µL of CEDMSDEA reagent and 45 µL of ethyl acetate are added. The solution is shaken briefly and within 5 min, 1 µL of the extract is injected into the gas chromatograph.

Suitable GC conditions\(^{(81)}\) are as follows. Instrument: GC/NPD or GC/MS. Capillary column: 15 m × 0.23 mm ID DB-1 (SE-30) capillary column. Carrier gas is helium and the injector is used with an initial split ratio of 32:1. The oven temperature is programmed from 180 °C to 208 °C at 3 °C min\(^{-1}\) followed by 10 °C min\(^{-1}\) to 250 °C. Injection port, detector (NPD) and source (MS) temperatures are set to 275 °C, 300 °C and 220 °C, respectively. When using NPD detection, helium is used as make-up gas at a flow of 30 mL min\(^{-1}\) and the flow rates of hydrogen and air at the detector are 2.6 and 100 mL min\(^{-1}\), respectively.

**Silylation with N-(tert-Butyldimethylsilyl)-N-methyltri-fluoroacetamide.** This derivatization procedure is according to Heberer and Stan.\(^{(83)}\) An aliquot of a standard solution or sample extract (about 1 mL) is dried under a gentle stream of nitrogen in a sample vial. The residue is dissolved in 50 µL of acetonitrile, then 50 µL of MTBSTFA are added. The derivatization is carried out in sampling vials which are capped with a Teflon®-lined sampler cap and placed in a drying cabinet at 80 °C for 1 h. The mixture is cooled to room temperature and the vials are decapped. The solution containing the derivatives is transferred to 200-µL vial inserts and 1 µL is injected directly in the gas chromatograph.

Suitable GC conditions are as follows. Instrument: GC/MS. Capillary column: 25 m × 0.2 mm ID × 0.33 µm HP-5 capillary column fitted with a 1.5 m × 0.32 mm ID × 0.33 µm HP-5 precolumn. The carrier gas is helium (purity: 99.999%) set to a flow of 28 cm s\(^{-1}\) at the initial temperature. The oven temperature is held at 100 °C for 1 min following injection, then programmed at 30 °C min\(^{-1}\) to 150 °C, which is held for 1 min, then at 3 °C min\(^{-1}\) to 205 °C followed by 10 °C min\(^{-1}\) to 260 °C and finally held for 23 min. Injection port and interface temperatures are set to 230 °C and 250 °C, respectively. Samples are injected using hot splitless injection with the split closed for 0.9 min.

### 3.1.2 Gas Chromatography with Electron Capture Detection

GC with ECD has been used successfully for many years, especially, in trace level analysis of chlorinated pesticides. Analysis by GC/ECD still belongs to the most sensitive detection methods and is the yardstick for other analytical instruments. Many acidic pesticides are substituted with hetero atoms, mostly chlorine, which make them suitable for ECD. Thus, even the methyl esters can be analyzed by GC/ECD. When using methyl, ethyl or butyl chloroformates for derivatization, it is possible to identify and confirm acidic pesticides using only one GC column as shown in Figure 1. In this case, the shift of the retention times caused by introducing a methyl, ethyl or butyl moiety into the individual molecule is used for analyte identification.

**Figure 1** ECD chromatograms of a standard mixture containing 13 acidic pesticides as their (a) methyl, (b) ethyl and (c) butyl esters. One nanogram of each compound has been analyzed. 1, dichlorobenzoic acid; 2, clopyralid (24); 3, dichlorprop (4); 4, 2,4-D (2); 5, triclopyr (40); 6, fenoprop (5); 7, 2,4,5-T (9); 8, 2,4-DB (3); 9, picloram (33); 10, fluazifop (28); 11, haloxyfop (31); 12, flamprop (27); 13, acifluorfen (20). (Reprinted from Butz, Stan, J. Chromatogr., copyright (1993),\(^{(83)}\) with permission from Elsevier Science.)
As mentioned before, there is one drawback that all alkyl derivatives have in common; they present some problems in ECD detection of lower chlorinated analytes, e.g. mecoprop (8), MCPA (6) or MCPB (7). Alkyl esters of acidic pesticides such as bentazone (10) or 2-(1-naphthyl)acetic acid (32) are not detected by GC/ECD at all.

Lee et al.\(^6\) compared the relative response factors (RRFs) of methyl, trichloroethyl (TCE), pentafluoropropyl (PFP) and PFB derivatives of 13 acidic herbicides applying GC/ECD detection. The RRFs of the PFB esters were found to be twice as large as those of the corresponding TCE esters and much higher than those of the PFP or even the methyl esters. The RRFs of the MCPA methyl or PFP ester were very low, thus both derivatives were found to be inapplicable to the determination of MCPA and other monochlorinated herbicides by GC/ECD at residues levels.\(^6\) On the other hand, trichloroethanol did not react with bromoxynil (13), and the yield of the 2,3,6-TBA (39) TCE ester was poor. Therefore, Lee et al.\(^6\) concluded that the PFB esters were the derivatives best suited to the simultaneous determination of all 13 herbicides at trace levels applying GC/ECD. PFB esters increase the sensitivity of ECD detection tremendously and they allow the determination of acidic pesticides independent of their substitution by chlorine. As an example for multiresidue analysis, Figure 2 shows an ECD chromatogram of a standard mixture of 17 acidic pesticides as their PFB esters, amides and ethers.

A major drawback of the PFB ester procedure is the large number of interfering substances in the extract from the environmental matrix when the extract is analyzed by GC/ECD.\(^28,64,75\) Figure 3 shows the ECD chromatogram of a derivatized extract of a drinking water sample measured without additional cleanup procedures.

As described by Lee et al.,\(^6\) the analysis of derivatized sample extracts by GC/ECD often needs time-consuming cleanup procedures using gel permeation chromatography (GPC) and/or silica-gel columns. Therefore, the screening of PFB derivatives using GC/MS or using GC/AED has great advantages compared to conventional GC/ECD methods.
3.1.3 Gas Chromatography with Mass Spectrometry and Gas Chromatography with Tandem Mass Spectrometry

The coupling of GC to MS has greatly benefited from the development of fused silica capillary columns and the development of small, relatively inexpensive mass spectrometers as dedicated GC detectors. GC/MS instruments which are easy to use and easy to maintain are now readily available to residue chemists. Thus, specialists in MS are no longer a prerequisite for GC/MS operation. MS is the most sensitive method of molecular analysis yielding information on the molecular weight (MW) as well as the structure of the analytes. When GC and MS are directly combined into one GC/MS system, the capabilities of that system are not merely the sum of the capabilities of these two outstanding analytical methods; the increase in analytical information is exponential. Extreme selectivities can be obtained which are of great importance in screening analysis of target analytes in environmental samples.

Positive identification of pesticide residues in environmental samples (soil or water) at trace level concentrations confronts the analyst with a number of problems. The high sensitivity and selectivity of modern GC/MS instruments enable the detection of the analytes at the parts per billion (µg L\(^{-1}\) or µg kg\(^{-1}\)) or even at the parts per trillion or parts per quadrillion (pg L\(^{-1}\) or pg kg\(^{-1}\)) (ng L\(^{-1}\) or ng kg\(^{-1}\)) level, depending on the matrix and in particular on the chemical structure of the pesticide.

In the beginning, GC/MS was mostly used for the confirmation of results positively monitored with screening methods using less selective detectors such as ECD or NPD. Nowadays, screening for pesticides in environmental samples with full scanning as well as target compound analysis applying SIM programming is becoming more and more popular for the multiresidue analysis of acidic pesticides. GC/MS analysis is sometimes unavoidable because some analytes which do not contain chlorine, fluorine or bromine atoms, such as the methyl esters of bentazone (10) or 2-(1-naphthyl)acetic acid (32), are not even applicable to common GC/ECD analysis and often GC/ECD analysis of environmental samples is heavily disturbed by matrix interferences which mostly do not interfere with GC/MS analysis.

3.1.3.1 Electron Ionization Mass Spectrometry Measurements

With most modern instruments, full scan spectra can be obtained at the low nanogram or even at the picogram level. Combined with suitable sample preparation methods, as shown in section 4.1.1, these detection limits are sufficient for the analysis of trace level concentrations of pesticides in water samples at the microgram per liter or even down to the nanogram per liter level. Using GC/MS with SIM programming (see section 3.1.3.2) acidic pesticides can be analyzed at much lower concentrations comparable to ECD detection. A prerequisite for GC/MS analysis is, however, knowledge of the mass spectral properties of the analytes, i.e. knowledge about important peaks (molecular ions and dominant fragments) and their corresponding intensities in the individual mass spectrum. Commercially available mass spectral libraries contain the EI mass spectra of up to 275 000 compounds, for example the WILEY library, and there are some smaller, more specialized libraries which contain mass spectra of pesticides, e.g. the HPPEST or the Pfieger, Maurer, Weber library.

The MS libraries contain, however, only few mass spectra of pesticide derivatives. In this section, some GC/MS chromatograms of derivatized multicomponent standard mixtures of acidic pesticides are shown. Additionally, mass spectral data have been collected for many acidic pesticide derivatives and important mass spectral features of these derivatives will be discussed.

Methyl Derivatives. Figure 4 shows the GC/MS chromatogram of a standard mixture of 17 acidic pesticides which have been methylated with diazomethane. Even the coeluting derivatives of fluroxypyr (30) (mass to charge ratio, \(m/z\) 209, 268, 270) and 2,4-DB (3) (\(m/z\) 59, 101, 262) can be identified and quantified by their characteristic ion traces as demonstrated in Figure 5.

This methylation shifts the MW of the analytes by 14 Da. Many of the methyl derivatives exhibit characteristic ions in their EI mass spectra. Exceptions are given by the mass spectra of the methyl derivatives of MCPB (7) and 2,4-DB (3) which exhibit only noncharacteristic ions with \(m/z\) 59 and 101 at high intensities, whereas the molecular ions are of low intensity not suitable for trace level analysis. Table 2 shows the three most indicative ions in the EI mass spectra of individual pesticide derivatives together with their relative intensities. This information, together with the retention times of the analytes, facilitates creation of time scheduled SIM programs for trace level target compound analysis as shown in section 3.1.3.2.

Pentafluorobenzyl Derivatives. Derivatization with PFBBr shifts the MWs of the acidic pesticides by 180 Da. The typical fragment ion in the EI mass spectra of all PFB derivatives is the resonance-stabilized pentafluorobenzylion at \(m/z\) 181, which is always accompanied by a smaller fragment ion at \(m/z\) 161 resulting from the cleavage of HF. As can be seen from Table 3 the characteristic pentafluorobenzylion often appears as a base peak in the mass spectra, especially with phenolic pesticides. It may be used as a “monitoring ion” for PFB derivatives in SIM programming (section 3.1.3.2),...
Figure 4 TIC (total ion current) chromatogram of a methylated standard mixture containing 17 acidic pesticides and the surrogate standard compound 2-(4-chlorophenoxy)butyric acid.

Figure 5 Indicative ion traces for fluroxypyr-methyl (m/z 268, 270 and 209) and 2,4-DB-methyl (m/z 59, 101 and 262) extracted from the TIC chromatogram in Figure 4.

but it is not selective and should not be used for identification and quantification of the pesticides. Most of the acidic pesticides exhibit other characteristic fragments or even high intensity molecular ions, which enable their analysis at trace level concentrations. Table 3 shows a compilation of the three most indicative ions in the EI mass spectra of the individual pesticide derivative together with their relative intensities.

Figure 6 shows the GC/MS chromatograms of a derivatized standard mixture and the derivatized extract of a fortified sewage farm groundwater sample. Both chromatograms were recorded by GC/MS applying SIM programming, as described in detail in section 3.1.3.2. Although the fortified sewage farm groundwater sample contains a bulk of matrix compounds, the sample chromatogram looks as transparent as the standard chromatogram. Thus, the identification and quantitation of all 16 acidic pesticides was possible at a concentration level of only 200 ng L$^{-1}$ by using the indicative ion traces.

Trifluoroethyl Esters. Table 4 shows the three most indicative ions in the EI mass spectra of the TFE (trifluoroethyl) esters of the individual pesticide together with their relative intensities.

tert-Butyldimethylsilyl Derivatives. Figure 7 shows the GC/MS chromatogram of a standard mixture of 15 acidic pesticides as their TBDMS derivatives. Derivatization with MTBSTFA shifts the MW of the analytes by 114 Da, except where the analytes are also derivatized a second functional group such as fluroxypyr and picloram (both +228 Da). The molecular ion is mostly weak or absent, but the EI mass spectra of the TBDMS derivatives exhibit very characteristic (M-57)$^+$ ions resulting from the cleavage of the tert-butyl moiety. This very intense peak also enables the determination of the MW for unknown compounds. Other characteristic mass fragments are (M-15)$^+$, from the cleavage of a methyl group, (M-114)$^+$, formed by the cleavage of the TBDMS group and (M-101)$^+$, resulting from the cleavage of the tert-butyl moiety and the additional loss of CO$_2$. Table 5 shows the three most indicative ions in the EI mass spectra of the individual pesticide derivatives together with their relative intensities.

\(^a\) Relative intensity of the ions in the full scan EI spectrum of the individual compound (base peak = 100).

3.1.3.2 Selected Ion Monitoring Since GC/MS with full scan often does not provide the sensitivity necessary to meet the maximum tolerances in drinking water or soil, GC/MS in SIM mode is applied to achieve lower detection limits. The increase in sensitivity is caused by the increase of the relative individual scan times (also called dwell times) which are spent detecting only indicative ions of the analytes.

GC/MS with SIM is commonly used for the confirmation of positive results obtained with conventional detectors such as GC/ECD. Following decreasing prices of GC/MS instruments, GC/MS with SIM is already in widespread use for screening analysis of pesticides in water. Multiresidue methods using SIM have gained much importance for trace level analysis of pesticides in environmental samples, especially with acidic pesticides. This may also be a consequence of the necessity to derivatize polar compounds prior to GC. Thus, only a limited number of derivatizable compounds has to be targeted. GC/MS with SIM acquisition is often a prerequisite for environmental trace level analysis because derivatized matrix compounds or by-products of the derivatization procedure often interfere with detection by conventional GC detectors.

Heberer et al. reported a method for the detection of more than 30 acidic pesticides as their PFB esters in a single GC run, applying GC/MS with SIM time window programming. In this method, three indicative ions from the mass spectrum were selected for each analyte and an appropriate retention time window for recording those ions was set. Table 6 shows the resulting SIM program used to produce the MID chromatogram, a summation of all ions in each corresponding time window, as shown in Figure 8. In this case, only 20 pg of each analyte were injected and analyzed by GC/MS with SIM. This amount is equivalent to a concentration of 1 ng L\(^{-1}\) in water analysis assuming 100% recovery of the analytes and a concentration factor of 10 000 being obtained when using the sample preparation procedure described in section 4.1.1. The identity of the compounds can be easily confirmed by extracting the ion traces of the indicative analyte ions.

In general, SIM programming can be used for the analysis of any compound which is amenable to GC. The only prerequisite for SIM programming is knowledge of the individual GC retention times, the indicative masses and their relative abundances in the mass spectra. All this information, including the indicative ions labeled as mass 1 to 3, is given in Tables 2 to 5 for the different derivatives of acidic pesticides. Using this information and recording a full scan chromatogram with a derivatized standard mixture to determine the retention times, the analyst is able to create a suitable GC/MS SIM program for multicompound trace level analysis. To take full advantage of the increase in detection sensitivity provided by the SIM technique, the indicative ions are only recorded in a time window in which the target compound is expected. The only problem with SIM programming is to find intervals in the chromatogram where switching from one window to the other can be performed without missing any of the target compounds. When creating a SIM method for the analysis of so many compounds in one GC run a compromise has to be found between the wish to have the smallest number of target compounds...

Figure 8 MID chromatogram recorded with GC/MS applying SIM programming of 34 acidic pesticides as their PFB derivatives (20 pg of each compound). For peak identification refer to Table 6. (Reprinted from Heberer et al., copyright (1994), with permission from AOAC International.)
in each window and the necessity of finding a sufficient gap in the chromatogram to enable window switching.\(^{(75)}\)

When using uniform dwell times within the individual SIM time windows the relative intensities of the various ions are comparable with the relative abundances in the full scan mass spectra as compiled in Tables 2–5. For analyte identification in environmental analysis, the peak area ratios of the indicative ions should match within ±20\% with the relative abundances of the standard compounds.\(^{(41)}\)

In trace analysis, the feature of an adjustable selectivity, as is possible using GC/MS with SIM acquisition, is very valuable and is not provided by a less selective detector such as an ECD.\(^{(75)}\) This feature is shown in Figure 9 with the chromatogram of a pentafluorobenzylated derivatization blank. The MID chromatogram of the indicative ions (top) shows a flat baseline with only one small peak in the entire chromatogram, whereas the ion trace of the pentafluorobenzylum ion (\(m/z\) 181) which appears in the mass spectra of all derivatized compounds (analytes and matrix as well) shows strong interference. These peaks represent impurities from the reagents and by-products formed during derivatization. Thus, this ion should not be included in trace level analysis of target analytes. It may, however, be additionally recorded and used as a “monitor ion” to obtain an overview of the matrix content or it might help to avoid missing another important peak from a derivatized nontarget analyte.

### 3.1.3.3 Negative Chemical Ionization

Negative chemical ionization (NCI) has been successfully used in environmental analysis for the selective and sensitive detection of electron capturing analytes such as organochlorine pesticides, polychlorinated biphenyls (PCBs) and dioxins.\(^{(89,90)}\) Applying GC/MS with NCI appears to be especially promising for the analysis of PFB esters of acidic pesticides. Meiring et al.\(^{(73)}\) described the analysis of 10 acidic pesticides as their PFB esters by applying GC with high resolution (HR) NCI/MS and SIM. Lee et al.\(^{(64)}\) used GC/MS applying EI and NCI in water analysis to confirm 14 acidic herbicides as their PFB derivatives, and Vink and van der Poll\(^{(78)}\) used NCI/MS to confirm eight acidic herbicides after GC/ECD analysis. Stan et al.\(^{(91)}\) analyzed more than 30 PFB esters of acidic herbicides applying electron capture NCI using ammonia as reagent gas.

NCI is a so-called “soft ionization” technique which in most cases produces intensive molecular anions and shows only little fragmentation. This ionization behavior has some advantages because the molecular anions often

![Figure 9 Derivatization blank of the pentafluorobenzylolation. (a) MID chromatogram of the indicative ions. (b) Ion trace of m/z 181. (Reprinted from Heberer et al.,\(^{(75)}\) copyright (1994), with permission from AOAC International.)](image-url)
have an excellent signal-to-noise ratio. On the other hand, low fragmentation may become a problem in trace level analysis because there are no suitable confirmational ions. However, many of the acidic pesticides are substituted by chlorine atoms and therefore show the characteristic chlorine cluster ions, which may also be used to confirm the individual compound.

In the case of the PFB esters, the molecular anions are missing in the NCI mass spectra because the PFB moiety easily cleaves from the molecule during the dissociative electron capture process.\(^{73,91}\) Thus, the base peaks in the mass spectra are formed by the anions of the original acidic pesticides \((\text{M}-181)^{-}\). Table 7 shows the prominent anions in the ammonia NCI mass spectra of the PFB esters for more than 30 acidic herbicides.

When measuring standard compound solutions, GC/NCI/MS was found to be on average ten times more sensitive than conventional GC/EI/MS. In full scan mode, detection limits between 10 and 100 pg per compound injected were determined.\(^{91}\) In SIM mode, mecoprop PFB ester could be detected down to 500 fg. For all compounds compiled in Table 7, the detection limits in SIM mode were estimated to be between 0.5 and 5 pg injected.\(^{91}\)

Unfortunately, these results could not be confirmed when measuring real water samples. The detection limits of GC/NCI/MS with SIM were found to be more than ten times higher than those determined with GC/EI/MS with SIM.\(^{91}\) In full scan mode the detection limit was on average 100 ng L\(^{-1}\), which is similar to or slightly better than that of full scan mode applying EI/MS. However, in

</table>
contrast to EI/MS with SIM, no significant improvement of the detection limits was observed for NCI/MS with SIM.\(^{(91)}\) The reason for this phenomenon lies in the selection of suitable anions for SIM programming. The masses of the prominent NCI anions of the PFB esters are much lower than those of the EI ions. Unfortunately, in environmental sample extracts the mass spectral background between \(m/z\) 200 and \(m/z\) 340 was found to be rather high in NCI/MS.\(^{(91)}\) The effective signal-to-noise ratio of the SIM anions was therefore much worse than that observed for the EI/SIM ions of the PFB esters. Thus, Lee et al.\(^{(64)}\) recommended extensive cleanup procedures in sample preparation and Meiring et al.\(^{(73)}\) recommended the use of GC with HR NCI/MS for low-level analysis of dirty samples after derivatization with PFBB Br. Owing to its selectivity HR/NCI/MS is not disturbed by coeluting matrix compounds. However, HR/MS instruments are rather expensive and need well-trained personnel. These instruments are therefore unlikely to be used for routine analysis of environmental samples. Another less expensive alternative is probably provided by low resolution NCI/MS detection using ion-trap MS instruments. This technique has, however, not yet been described for the analysis of acidic pesticides.

### 3.1.3.4 Tandem Mass Spectrometry Measurements

Another promising analytical approach for the sensitive and highly selective determination of acidic pesticides in environmental samples is the application of GC with MS/MS. For a long time, MS/MS was only possible using highly sophisticated, very expensive MS instruments such as triple stage quadrupole mass spectrometers. Today, MS/MS recording is, with a few restrictions, also applicable using relatively inexpensive ion trap mass spectrometers.

In MS/MS acquisition a “parent ion” from the original mass spectrum is selected and fragmented again by collision induced dissociation (CID) forming a daughter ion spectrum. When a suitable parent ion for the individual analyte is selected, the resulting daughter ion spectra are highly selective and unlikely to be disturbed by interfering compounds. The daughter ions mostly exhibit better signal-to-noise ratios, further enhancing the sensitivity of GC/MS analysis. In SRM mode only one or a few daughter ions are monitored for the individual compound. Thus, SRM gives maximum sensitivity and selectivity and, similar to SIM, a time-scheduled SRM programming for multiresidue analysis may be developed. The hardware and operation of MS/MS acquisition are described in more detail elsewhere.\(^{(24,25)}\)

MS/MS is already used in routine analysis to confirm positive analytical results and a few laboratories also make attempts to use MS/MS programming for multiresidue analysis of acidic pesticides using GC with ion trap MS. Such methods have not yet been validated over a longer time period in routine analysis, nor have they been published.

### 3.1.4 Other Detection Methods

#### 3.1.4.1 Gas Chromatography with Nitrogen–Phosphorous Detection

GC/NPD is frequently applied in environmental analysis to the determination of nitrogen or phosphorus containing pesticides such as triazine herbicides or organophosphorous insecticides. However, the use of GC/NPD for the determination of acidic pesticides has only been described by Bertrand et al.\(^{(81,82)}\) Acidic

![Figure 10](image-url)"
PHENOXY ACID AND OTHER ACIDIC PESTICIDES: SINGLE CLASS, MULTIVERSED ANALYSIS OF

pesticides are originally unsuitable for NPD analysis, but derivatization with CEDMSDEA (see section on Silylation with (2-cyanoethyl)dimethyl(diethylamino)silane) introduces nitrogen into the molecules which renders the derivatives suitable for NPD analysis. Figure 10 shows the resulting GC/NPD chromatogram of a derivatized standard mixture.

3.1.4.2 Gas Chromatography with Atomic Emission Detection AED is a highly sophisticated and still very expensive technique which provides high element specific detection of all compounds amenable to GC. In theory, a GC/AED can detect any element in the periodic table except for helium. Unlike the ECD, the AED can also distinguish between fluorine, chlorine, bromine, and iodine. As most modern pesticides contain hetero atoms such as sulfur, phosphorus, nitrogen, chlorine, bromine or fluorine, GC/AED is most suitable for pesticide analysis. However, for practical reasons, it is not always possible to determine all the element traces in one single GC run. Thus, carbon, hydrogen, chlorine, and bromine may be detected in a single GC run or alternatively carbon, nitrogen and sulfur can be monitored simultaneously. Since molecules are fragmented into their constituting elements, these can be quantified individually by external calibration. Thus it is possible to estimate the sum formula of an unknown compound. Several excellent reviews have been written which describe the hardware, the techniques, some applications and limitations of the AED.

A major drawback of the AED in trace level analysis is the lack of sensitivity, especially for the important nitrogen or oxygen traces. This drawback may be overcome by using large volume injection techniques such as PTV. Stan and Linkerhager demonstrated the analysis of 22 acidic compounds including 19 pesticides as their PFB esters at trace level concentrations applying GC/AED. Table 8 compiles the retention times, molecular formula and detection limits in water analysis for the individual element traces applying GC/AED with PTV injection of 12.5 µL of a derivatized sample extract. The samples (1 L each) have been prepared according to the procedure described in section 4.1.1, therefore the amount injected using PTV corresponds to an aliquot of 125 mL of a water sample. Figure 11 shows a set of element-specific chromatograms obtained for a derivatized standard solution containing the analytes. All analytes are detected with the element traces reflecting their elemental composition.

*a LOD (limit of detection) of the multiresidue methods using SPE with RP-C₁₈ (reversed-phase octadecyl) adsorbent as described in section 4.1.1.
Figure 11  GC/AED chromatogram of the hetero element traces of an acidic herbicide standard mixture (1 ng µL⁻¹) derivatized with PFBBr; 12.5-µL cold split PTV-injection with solvent venting. Peak numbering as given in Table 8. (Reproduced from Linkerhänger* by permission of Shaker Verlag.)
of chlorine, bromine and sulfur show the AED to be much more sensitive to these than to nitrogen, oxygen or fluorine. Thus the AED seems to be well suited to trace level analysis of compounds containing these heteroatoms, including most acidic pesticides. Other compounds such as 2-(1-naphthyl)acetic acid (32) are much more difficult to analyze as can also be seen in Figure 11. Here, 2-(1-naphthyl)acetic acid PFB-ester (peak no. 11) can only be detected in the oxygen or fluorine trace, both of which are heavily disturbed by matrix peaks when analyzing pentafluorobenzylated extracts of real water samples.

3.2 High-performance Liquid Chromatography

HPLC is well suited to the direct and nondestructive analysis of contaminants which are originally not amenable to GC analysis such as thermally unstable and highly polar pesticides or conjugated metabolites. HPLC analysis does not require any preliminary derivatization steps for the separation of acidic pesticides, and pesticide metabolites can often easily be included in the analytical method, see section 3.2.1. HPLC indeed appears to be the most appropriate technique for the determination of these analytes. HPLC is, however, less useful for screening purposes in multiresidue analysis than GC, mainly because of its relatively low separation efficiency. Matrix compounds such as humic acids often interfere because they co-elute with the polar analytes.

In the past, a major drawback of HPLC was the difficulty in coupling LC (liquid chromatography) to sensitive and selective detectors. Progress in coupling LC to MS has improved the possibilities of identification and confirmation of analytes at trace level concentrations. Some applications of HPLC to the analysis of acidic pesticides will be described in the following sections.

3.2.1 Conventional Detection Methods

(High-performance Liquid Chromatography with Ultraviolet, Diode Array Detection, Fluorescence Detection and Electrochemical Detection)

HPLC with conventional ultraviolet (UV) or diode array detection (DAD) is one of the most frequently applied methods for the analysis of acidic pesticides in water samples. Additionally, fluorescence detection (FLD) and electrochemical detection (ELCD) have been used to lower the detection limits of HPLC analysis. Figure 12 shows the separation of a standard mixture of acidic pesticides, including bentazone (10) and two of its hydroxylized metabolites using HPLC with DAD.

A major drawback of using UV detection or DAD is that both are often prone to matrix interferences. At wavelengths below 300 nm a huge background level from humic substances and other naturally occurring dissolved organic compounds hampers trace analysis of polar analytes. Figure 13 shows a typical HPLC chromatogram of a water sample where the early eluting polar analytes are completely masked by equally polar humic substances. Additionally, in HPLC analysis with UV detection, there is a tremendous risk of false positive results because peak identification is virtually based only on retention times. This latter statement also applies to HPLC analysis using DAD spectra, because these often suffer from interference at lower wavelengths. In
In general, the information content of DAD spectra is not comparable to MS spectra. In conclusion, HPLC with UV or DAD detection often does not provide the sensitivity and the degree of confidence which is absolutely necessary in acidic pesticide monitoring.

3.2.2 High-performance Liquid Chromatography with Mass Spectrometry and Tandem Mass Spectrometry

A variety of HPLC/MS techniques using thermospray (TSP) and particle beam (PB) interfaces have been examined in order to develop a rugged system with the necessary sensitivity and selectivity for trace level analysis of acidic pesticides in the environment.\(^\text{110,119–123}\) However, it was found that the behavior and sensitivity of these techniques may vary considerably depending not only on chemical and physical properties of the individual pesticide, but also on instrumental and analytical conditions.\(^\text{73}\) Another major limitation of LC/MS methods such as TSP/MS using CI processes is the lack of information for MS confirmation. Thus, Geerdink et al.\(^\text{122}\) used TSP MS/MS applying the SRM mode to overcome this problem and to lower detection limits. PB interfaces allow both chemical and electron ionization. As discussed in the GC section, EI mass spectra often contain many fragments which are suitable for analyte confirmation purposes. A major drawback of PB interfaces is, however, the lack of sensitivity, which has been overcome to a certain degree using specially designed micro HPLC/PB/MS instruments.\(^\text{123}\) Figure 14 shows the total ion PB/MS chromatogram recorded with EI for a standard and a soil sample spiked with acidic pesticides at a concentration of 33.3 ppm. It should be noted that both ionization techniques (PB- and TSP/MS) require much experience, method validation and time for instrument maintenance.

Newer LC/MS interface types, especially API interfaces increased sensitivity and made instrument maintenance and analysis much easier. API is a term covering two different principles of ionization, electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI). ESI is a soft ionization technique which typically generates only ionized molecular ions \([M + H]^+\) (in positive mode) and \([M – H]^–\) (in negative mode). The latest developments, fundamentals, instrumentation and applications of ESI/MS have been described in a monograph by Cole.\(^\text{124}\) The first applications of ESI- and APCI-interfaces for the analysis of acidic pesticides applying HPLC/MS with time-scheduled SIM have been described.\(^\text{125–129}\) Figure 15 shows a TIC chromatogram recorded with HPLC/APCI/MS of a river water sample spiked with a mixture of acidic pesticides. (Reprinted with permission from Kim et al., *Anal. Chem.*,\(^\text{121}\) copyright (1991), by American Chemical Society.)

3.3 Other Techniques

3.3.1 Capillary Zone Electrophoresis

Several of the phenoxy acid herbicides are chiral, e.g. those with the phenoxy substituent on the 2-position of propionic acid, and therefore exist as a pair (racemic
mixture) of optical isomers called enantiomers. It has been recognized that only the $R$ enantiomers show herbicidal activity and since the 1980s enantiopure products have been developed, registered and now replace the earlier used racemic mixtures in many countries. On the other hand, it has been shown that enantioselective separations is also involved in biotic pesticide degradation processes. Using high-performance capillary electrophoresis (HPCE) or CE it is possible to distinguish between the different enantiomers of phenoxy acid herbicides. Figure 17 shows the electropherograms of the enantiomeric separation of some acidic herbicides.

Garrison et al. called the phenoxy acids “excellent candidates” for separation by CE, because their $pK_a$ values allow separation by the simplest form of CE called capillary zone electrophoresis (CZE) which separates only charged species. However, enantioselective separation of different acidic pesticide derivatives has also been described applying HR GC/MS and the enantiomers of mecoprop and dichlorprop have also been separated by HPLC using columns with chiral solid phases.

Several applications of CE for the analysis of acidic herbicides have been reported. A major drawback of CE analysis is, however, the insufficient sensitivity of commonly used CE techniques applying only to small sample volumes and UV detection which make them unsuitable for trace level analysis of acidic pesticides in environmental samples. Nielen applied CE with field-amplified injection after SPE for the analysis of phenoxy acid herbicides in water at sub parts per billion levels. Jung and Brumley as well as Mechref and Rassi produced fluorescent derivatives of phenoxy acid herbicides and applied CE with laser-induced fluorescence (LIF) detection for trace level analysis down to 0.2 ppb in water samples. Although the detection limits of these CE methods are still much higher than those of other methods, e.g. GC/MS, CE adds an interesting separation tool to the more conventional chromatographic instrumentation. Furthermore, the coupling of CE to API/MS (MS/MS) is a new and promising approach for the trace level analysis of acidic pesticides. Compared to UV detection, MS/MS detection is not impaired by matrix interferences and will also enhance the level of confidence in analyte identification.

### 3.3.2 Automated Multiple Development Thin-layer Chromatography

AMDTLC is a modern variation of classical TLC which offers much higher separation power than conventional TLC methods. In several reviewing articles the principles, hardware and some applications of AMDTLC in environmental analysis have been described. Conventional TLC is not sufficient to separate pesticides from complex matrix compounds as found in environmental samples. AMDTLC instruments are fully automated to process several chromatographic runs consecutively. Drying steps are included between the different TLC runs to remove the mobile phases of the previous runs from the TLC chamber and plate. Thus, it is possible to change the solvents from one run to the other slowly to produce a solvent gradient comparable to HPLC, but in contrast to HPLC it is also possible to change the conditions dramatically, e.g. from acidic to basic eluents. In AMDTLC, the efficiency of the separation

---

Figure 15 TIC chromatogram recorded with HPLC/ESI/MS of an extract of a river water sample fortified with acidic herbicides at a concentration of 0.5 µg L⁻¹: 1, dicamba; 2, bentazon; 3, 2,4-D; 4, benazolin; 5, coumafuryl; 6, bromoxynil; 7, DNOP; 8, warfarin; 9, MCPA; 10, 2,4,5-T; 11, ioxynil; 12, mecoprop; 13, dichlorprop; 14, 2,4,5-T; 15, MCPB; 16, 2,4-DB; 17, dinoseb; 18, fenoprop; 19, dinoterb; 20, PCP. PHENOXY ACID AND OTHER ACIDIC PESTICIDES: SINGLE CLASS, MULTIRESIDUE ANALYSIS OF

is increased remarkably compared to common isocratic elution because the total distance migrated by the solvent front is in the meter range when all individual TLC runs are summed up. The most important feature of AMDTLC which enhances the separation power of this technique tremendously is the so-called “focusing effect”. During each run, the lower edge of a chromatographed spot is reached first by the solvent front and it begins to migrate to the upper edge of the spot which cannot move until it is wetted by the solvent. Thus, diffusion of the compound spots is suppressed and the analytes are concentrated in sharp peak bands on the TLC plate. It is a prerequisite that the AMD elution gradient always starts with a polar eluent (e.g. methanol) and ends with a nonpolar eluent (e.g. hexane) when using normal-phase silica gel TLC plates. The developed TLC plates are analyzed using a TLC scanner which allows the recording of UV spectra that can be used for confirmation of the analytes.

Butz and Stan applied AMDTLC for the screening in water of 265 pesticides including some acidic herbicides. For the analysis of acidic pesticides, detection limits between 5 and 15 ng have been reported for this method. Figure 18 shows the AMDTLC chromatogram of a pesticide mixture. Using sample preparation techniques with concentration factors up to 10,000, as will be described in section 4.1.1, it is also possible to meet the EU (European Union) maximum tolerances of 100 ng L\(^{-1}\) per pesticide in drinking water.

The AMDTLC technique has, however, some drawbacks:

1. The separation power is not comparable to GC.
2. UV detection is not as sensitive as other detection methods, e.g. GC/ECD, GC/MS or HPLC/MS/MS.
3. UV detection is prone to matrix interferences, e.g. by humic acids (as described in section 3.2.1).
4. UV spectra are not comparable to EI mass spectra with respect to information content or selectivity.
5. In contrast to GC, HPLC or CE columns, TLC plates represent an open chromatographic system which requires special care in handling.
6. AMDTLC equipment is, despite its apparent simplicity, relatively expensive.

A new approach is the on-line coupling of HPLC and AMDTLC which has not yet been applied to acidic pesticides. In combination, the separation power of both techniques can be enhanced remarkably, but some of the drawbacks mentioned, such as problems in analyte detection, remain.

4 ENVIRONMENTAL APPLICATIONS

Environmental analysis always consists of three important steps, namely sample collection and handling, sample preparation and finally instrumental analysis. All these steps are equally important and errors in sample collection cannot be corrected in the laboratory. Thus, proper collection and handling of samples is an essential part of producing meaningful analytical results, especially at
trace level analyte concentrations. As far as sample preparation is concerned, it has two functions in environmental analysis: (1) extraction of the analytes from the sample matrix and (2) enrichment of the analytes to a concentrated extract. All parts of the analytical procedure have to be combined, optimized and validated to achieve good laboratory practice (GLP). Sample preparation procedures which can be combined with any of the above instrumental analytical methods are described in the following sections. Nevertheless, some recommendations will help to enable the trace level determination of the acidic pesticides with the highest possible level of confidence, independent of the sample matrix.

### 4.1 Analysis of Water Samples

In Europe, the identification and quantitative analysis of acidic pesticides at a concentration level of 100 ng L\(^{-1}\) in drinking water for a single compound is required to meet the maximum tolerances set by the European Community’s drinking water regulation. In order to determine acidic pesticides at such low tolerance levels, the target compounds have to be extracted and enriched from the water sample with high recovery rates and concentration factors up to 10,000. Åkerblom\(^{146}\) gave an excellent overview of recent techniques and procedures for the extraction and cleanup of water samples in pesticide analysis.

In the past, several analytical methods were described using conventional LLE with dichloromethane, diethyl ether, ethyl acetate, ethyl acetate or benzene. \(^{69}\) Recently, SPE has been gaining much popularity in environmental water analysis. SPE has some striking advantages:

1. It enables concentration of high sample volumes.
2. It may also be used for sample cleanup.
3. It needs only small solvent volumes for analyte elution.
4. It is less toxic.
5. A high degree of automation is possible.
6. It saves labor and time, because some samples can be prepared in parallel.
7. It is usually less expensive.

A variety of SPE materials are commercially available and have been successfully used for the extraction of acidic pesticides. Most publications describe the use of modified silica gels, especially RP-C18 adsorbents. \(^{34,37,40,53,72,74 – 76,78,102,110,117,120}\) The use of the polymeric materials Amberlite XAD-4, \(^{61}\) PLRP-S, PRP-1, \(^{104,108,110,114}\) ion exchanging adsorbents, \(^{38,57}\) graphitized carbon black adsorbents \(^{115,125,127,128}\) or even a combination of Carbopack B/SAX \(^{103}\) has also been described. The flow chart in Figure 19 gives an overview of possible combinations of sample preparation, derivatization and instrumental analysis which can be applied for the determination of acidic pesticides in water.

At present, SPE using RP-C18 seems to be state of the art for the extraction of acidic pesticides from water samples. Therefore, it will be part of the application example described in the following section.

#### 4.1.1 Sample Preparation

The flow chart in Figure 20 depicts an example of a sample preparation procedure for the determination of acidic pesticides in water. This procedure applies SPE with RP-C18 adsorbent, derivatization with PFBBz and GC/MS applying full scan and/or SIM acquisition for analyte detection. Derivatization with PFBBz is described in detail in the section on Pentafluorobenzylation. GC/MS detection applying SIM is carried out using the parameters described in sections on Pentafluorobenzylation, Pentafluorobenzyl Derivatives and section 3.1.3.2 on SIM.

Sample concentration factors up to 10,000 are possible, but sample volumes should be reduced at higher matrix loads to avoid blocking of the SPE cartridges, especially when analyzing surface or even sewage samples. As discussed in section 3.1.1, the choice of the derivatization procedure, as prerequisite for GC determinations applying GC, depends on individual requirements such as the range of compounds which have to be analyzed, the GC detection method and the detection limits required. The use of GC/MS or GC/MS/MS is not always necessary but is recommended when analyzing environmental samples. In general, SPE can be combined with any instrumental method, but the use of GC/MS (or MS/MS) or HPLC/MS/MS for analyte detection is superior in achieving low detection limits, lower matrix interferences and a higher degree of confidence in the analytical results.

Some key conditions have to be considered in applying SPE to the extraction of acidic pesticides from water samples. Samples need to be acidified to a pH < 2 to obtain the undissociated form of the acidic pesticides, otherwise the acidic analytes will not be retained significantly by the nonpolar reversed-phase adsorbent and recovery rates will be low. Nowadays, a variety of RP-C18 materials is commercially available, nonendcapped materials with lower carbon load and some residual active silanol groups have proven to be best suited for the extraction of acidic pesticides. Other important conditions in sample preparation are the conditioning of the SPE cartridges, the percolation velocity, the drying step and the choice and volume of the elution solvent. Some acidic pesticides are applied as their esters in agricultural use. Most of them are easily hydrolyzed into the active acid form in...
PHENOXY ACID AND OTHER ACIDIC PESTICIDES: SINGLE CLASS, MULTIRESIDUE ANALYSIS OF

Figure 19 Possible analytical instrumentation for the multiresidue analysis of acidic pesticides in water. In bold: principle of the analytical procedure described in section 4.1.1. SDB, styrenedivinylbenzene.

Figure 21 shows the MID chromatogram of a drinking water sample extract spiked with a mixture of more than 30 acidic pesticides at a concentration level of only 10 ng L\(^{-1}\). All analytes could be detected unequivocally although this concentration is far below all maximum tolerance levels set for pesticides in drinking water. This example shows that multiresidue analysis of acidic pesticides can meet the European maximum

the environment, but to include the parent compounds it may also be necessary to introduce a hydrolytic step such as alkaline hydrolysis before extraction.\(^{146}\) According to Åkerblom\(^{146}\) phenoxy acids, ioxynil (14), flamprop (27), and fluroxypyr (30) are gently cleaved at pH 12 by standing overnight at ambient temperature.

4.1.2 Recoveries, Limits of Detection and Limits of Quantitation

As compiled in Table 9, most acidic pesticides can be extracted and determined at trace level concentrations down to the low nanograms level from water samples applying SPE and GC/MS detection with SIM.\(^{75, 76}\) Low recoveries were only observed for the indolylalkanoic acids, picloram (33) and flurenol (29). Fortunately, apart from picloram the other three compounds have no agricultural importance as pesticides.
tolerance levels of 100 ng L\(^{-1}\) in drinking water.\(^{(1)}\) In modern pesticide analysis, it is possible to achieve limits of detection (LODs) and also limits of quantitation (LOQs) clearly below 100 ng L\(^{-1}\) in many different kinds of matrices such as drinking, ground, surface or even sewage water\(^{(75,76)}\) as will be described in section 4.4.

The use of new, more “polar” RP-C18 adsorbents further enhanced the recovery rates and accuracy of SPE for acidic pesticides. These adsorbents are so-called nonendcapped materials (e.g. BAKERBOND C-18 Polar Plus or LiChrolut\textsuperscript{\textregistered} RP-select B) with lower carbon load and some residual active silanole groups. They have proven to be best suited for the extraction of acidic pesticides. Table 10 shows a comparison between different adsorbents for the extraction of some acidic analytes. An alternative to the commonly used reversed-phase adsorbents are polymeric adsorbents which have gained much importance for the extraction of polar analytes. Pichon et al.\(^{(114)}\) achieved high recoveries using polymeric adsorbents for the extraction of acidic pesticides at pH 7. The advantage of an extraction at neutral pH is that the fraction of naturally occurring humic acids

---

**Figure 20** Flowchart showing a suitable procedure for the trace level analysis of acidic herbicides in water.
which is not soluble at pH values >2 does not interfere with sample analysis, especially when applying HPLC. Fulvic acids are, however, also soluble at neutral pH, thus cleanup of sample extracts may still be necessary.

### 4.2 Analysis of Soil Samples

Several analytical methods have been reported for the analysis of acidic pesticides in soil samples.\(^{(38,41,49,54,66,77,82,121)}\) In particular, the methods of Lee et al.,\(^{(66)}\) Bruns et al.\(^{(41)}\) and Heberer and Stan\(^{(77)}\) have been developed for trace level analysis with LODs of less than 10 \(\mu\)g g\(^{-1}\) (ppb). Lee et al.\(^{(66)}\) described the extraction of ten acidic herbicides from soil samples acidified with \(\text{H}_2\text{SO}_4\) to a pH < 1. In this method a mixture of acetone and hexane (1 + 1) was used for extraction followed by liquid/liquid partitioning with dichloromethane.

and evaporation to dryness. The analytes were derivatized with PFBBR (see section on Pentafluorobenzylation), the resulting extract was cleaned up by silica gel column fractionation and determined by GC/ECD (see section 3.1.2). In their method for the extraction of acidic herbicides from soil samples, Bruns et al.\(^{41}\) used a mixture of acetone, distilled water and acetic acid (80 + 19 + 1) and a second extraction with 0.1 N KOH. This was followed by liquid/liquid partitioning with dichloromethane, evaporation, derivatization with diazomethane (see section on Methylation with Diazomethane) and GC/MS detection with SIM (see section on Methyl Derivatives and section 3.1.3.2 on SIM). Bruns et al.\(^{41}\) found GC/MS detection applying SIM to be indispensable in achieving the necessary reliability of the analytical results for trace level concentrations. Heberer and Stan\(^{77}\) tried to combine the advantages of both methods and invented SPE for analyte enrichment and sample cleanup as well. The resulting method allowed the analysis of dichlorprop (4), mecoprop (8), clofibric acid and naphthylacetic acid...
4.2.1 Sample Preparation and Cleanup Procedures

The method for the analysis of acidic pesticides applies acidic extraction, SPE, derivatization with PFBBr and GC/MS detection with SIM. An additional cleanup step by GPC was found to be useful to protect the gas chromatographic system from matrix contamination. It was, however, found not to be necessary because of the high selectivity of GC/MS detection with SIM.

4.2.1.1 Sample Extraction

A 50-g portion of wet soil is weighed into an Erlenmeyer flask and 200 ng of the surrogate standard (e.g., 2,4-D<sub>d6</sub> or 3,4-D) are added to the sample. Then 120 mL of the extraction solvent acetone–water–acetic acid (80 + 19 + 1; v/v/v) is added and the top of the Erlenmeyer flask is covered with aluminum foil and shaken overnight. After centrifuging the sample at 3000 rpm for 5 min, the supernatant is filtered into a round flask. Then 50 mL of the extraction solvent is added and the sample is re-extracted by ultrasound, centrifugation and filtration of the supernatant into the round flask again. The combined extracts are evaporated to approximately 20 mL by means of a rotary evaporator and approximately 180 mL of distilled water is added to this extract.

4.2.1.2 Solid-phase Extraction

SPE is carried out according to the procedure described in section 4.1.1.

4.2.1.3 Derivatization

Derivatization is carried out according to the procedure described in the section on Pentafluorobenzylation. The resulting extract is analyzed directly by GC/MS. Alternatively, the dried sample residue is dissolved in 1.5 mL of cyclohexane/ethylacetate (50/50; v/v) and this extract is used for further cleanup by GPC.

4.2.1.4 Gel Permeation Chromatography (Optional)

A 1-mL portion of the sample extract is transferred to the GPC column by means of a 1-mL injection loop. The first 20 mL of the GPC eluate (dump volume) is discarded, the fraction between 20 and 38 mL (collect volume) is collected and the GPC column is washed with another 25 mL. The collected fraction is evaporated to dryness by means of a rotary evaporator. Then the remaining residue is dissolved in 100 µL of toluene, transferred into a microvial and directed to GC/MS analysis.

4.2.1.5 Gas Chromatography/Mass Spectrometry Detection

GC/MS detection applying SIM is carried out using the parameters described in sections on Pentafluorobenzylation and PFB Derivatives and section 3.1.3.2 on SIM.

4.2.2 Recoveries, Limits of Detection and Limits of Quantitation

The recovery rates, LODs and LOQs of a few acidic analytes including dichlorprop (4) and mecoprop (8) are compiled in Table 11. The LOQs are all below 1 µg kg<sup>−1</sup> (ppb) soil for these analytes and the recovery rates were all better than 90% even at the lowest of the spiked concentrations of only 1 ppb. Figure 22 shows the resulting MID chromatogram of a derivatized extract of a soil sample fortified with 1 ppb of each analyte. The method may also be extended for the analysis of some other acidic pesticides.

4.3 Interferences

Common interferences in environmental analysis of polar contaminants often derive from natural compounds such as fatty acids or humic acids which occur in water or soil samples at concentrations much higher than those of the analytes. As a consequence, some analytical methods require extended cleanup procedures for sample extracts. In particular, analysis of matrix prone ground or surface water by HPLC with UV or DAD (section 3.2.1) or GC/ECD (section 3.1.2) may suffer heavy interference. Thus, the use of more selective methods is recommended.

detection methods such as MS, MS/MS or AED is often necessary to produce reliable results. Nevertheless, matrix interferences should also be avoided to protect the chromatographic system.

Although MS detection caused by its selectivity is not as prone to interferences as nonselective detectors, some considerations must be taken into account in method development, especially when applying SIM acquisition. Ions selected for SIM must be intense in the mass spectrum and must be indicative, meaning that all ions prominent in the mass spectrometric background, e.g. column bleed or common environmental contaminants such as phthalates and hydrocarbons, should be avoided. Interferences may occur in the GC chromatogram as discrete compound peaks (e.g. phthalates), in certain segments of the chromatogram or during the whole GC run. A compilation of possible background ions that may interfere in the analysis of the analytes is given in Table 12. Several authors tabulated ions, or published mass spectra of possible background interferences, e.g. solvents, various column coatings, silicon oils or hydrocarbons. Dependent on individual instrumental conditions, such sources of interference should be taken into account and avoided as far as possible.

Interfering matrix compounds can often be separated from the analytes prior to or during gas chromatographic analysis without introducing special time-consuming cleanup steps. Thus, the application of SPE was found to be more selective in separating the target analytes from matrix compounds than LLE. When using SPE for sample preparation, the choice of a suitable material is probably the first crucial step, other important details have already been discussed in section 4.1. In the past, SPE adsorbents of the same type were found to vary significantly in their ability to retain the analytes. Nowadays, most of the suppliers offer different

**Figure 22** MID chromatogram recorded with GC/MS applying SIM programming of a derivatized extract derived from a sediment sample fortified with 1 µg kg⁻¹ of each analyte. (Reprinted from Heberer and Stan, copyright (1996), with permission from AOAC International.)
adsorbents of the same type which are characterized as endcapped, nonendcapped and/or by different carbon loads (see also section 4.1.1). Sometimes considerable batch to batch variations in recoveries have also been reported with materials from the same supplier. Thus, in routine analysis or whenever larger sample series have to be analyzed it may be favorable to buy larger charges of adsorbents from the same batch to assure constant analytical quality.

When applying PFBBr for the derivatization of the acidic analytes, the use of toluene was found to have some advantages compared to commonly used acetone. The PFB derivatives of the acidic pesticides are easily dissolved in toluene while many coextracted matrix compounds such as humic acids remain underivatized and undissolved. Additionally, GC/MS analysis takes advantage of some properties of the PFB derivatives compared to the widely used methyl esters. By increasing the MWs of the analytes significantly (+180 Da) a better separation from coextracted matrix compounds is achieved which results in longer retention times. By recording ions with higher m/z values, a better detection selectivity is achieved when using EI/MS. Moreover, on a nonpolar GC-column (e.g. SE-54) molecules containing fluorine, such as the PFB derivatives, elute earlier than other molecules of similar molecular mass but without fluorine substitution.

Varying recoveries are often observed when a large amount of matrix is present in environmental samples, thus demanding better control of the sample preparation procedure. The use of suitable internal and/or surrogate standards is almost essential in environmental analysis of pesticides at trace level concentrations. The internal standard may be used to control the reproducibility of the derivatization and the operation of the gas chromatographic system which is also crucial for SIM programming when working with narrow time windows. The surrogate standard is added before analysis and may be used to control the whole analytical procedure including recovery control. Heberer et al. summarized the requirements for the properties of the surrogate standard as follows: (1) it should not be expected in environmental samples, (2) it should give high recoveries from fortified water samples and (3) it should be structurally similar to the most important target compounds. Thus, a suitable surrogate may be an isomer (e.g. 3,4-D or 2,3-D) or even better an isotopically labeled compound such as 2,4-D d₆.

4.4 Some Practical Applications

A few examples of positive findings of acidic pesticides and related polar contaminants are presented in this section to demonstrate the performance, sensitivity and potentials of multiresidue methods in environmental water analysis. The sensitivity of modern environmental analysis is demonstrated in Figure 23, showing the indicative ion traces (m/z 162, 414, 416) for dichlorprop PFB ester which were recorded for a derivatized sample extract applying GC/MS with SIM. In this case, dichlorprop (4) could be identified at a concentration level of only 0.5 ng L⁻¹ in a sewage water sample with a dissolved organic carbon content of about 70 mg L⁻¹. Even this small amount of dichlorprop extracted from one liter of sewage with a high load of organic matrix was identified by retention time and with the peak area ratios of the indicative ions matching the abundances listed in Table 3.

The performance and the potentials of multiresidue analysis of acidic pesticides applying GC/MS detection are demonstrated with the example of a derivatized river water sample shown in Figures 24 to 26.

Figure 23 Ion traces m/z 416, 416, 162 for dichlorprop (4) found at a concentration of only 0.5 ng L⁻¹ in a sewage water sample. (Reprinted from Heberer et al., copyright (1994), with permission from AOAC International.)
Figure 24 TIC chromatogram of a river water sample from the Havel near Berlin recorded with GC/MS in full scan mode (m/z 50–550). Sample spiked with 200 ng surrogate standard and 400 ng 2,4-dichlorobenzoic acid (ISTD) per liter. *Peaks resulting from matrix compounds overlapping the indicated target and standard compounds. (Reproduced from Heberer et al. by permission of Gordon and Breach Science Publishers.)

Figure 25 MID chromatogram recorded with GC/MS applying SIM programming of the river water sample from Figure 24. Sample with 74% recovery for the surrogate standard, containing 150 ng clofibric acid per liter. (Reproduced from Heberer et al. by permission of Gordon and Breach Science Publishers.)

Figure 26 Ion traces extracted from the MID chromatogram of the river water sample shown in Figure 25. (Reproduced from Heberer et al. by permission of Gordon and Breach Science Publishers.)
In the example shown in Figure 24, a TIC chromatogram of a typical river water sample recorded with GC/MS in full scan is presented, demonstrating how a high load of matrix gives a very complex chromatogram. The analyte clofibric acid labeled as 4-CP as well as the surrogate and the internal standard are overlapped by matrix compounds, although the occurrence of the peaks at the expected retention times already suggests their presence. In Figure 25, the corresponding MID chromatogram of the same river water sample recorded using GC/MS with SIM programming (section 3.1.3.2) is presented. The complex chromatogram resulting from full scan has turned into a clear chromatogram with the analyte peaks dominating. When examining the ion traces, as demonstrated in Figure 26, the signal-to-noise ratio is found to be excellent and the detection of the target compounds is not interfered with by matrix compounds. Thus, the 150-ng L\(^{-1}\) concentration of the analyte clofibric acid in the river water sample could be easily quantified. Clofibric acid is a phenoxy acid and a structural isomer of the herbicide mecoprop (8). Clofibric acid is, however, not used as a pesticide. It is the biologically active metabolite of blood lipid regulating pharmaceuticals.\(^{149}\) It is discharged as a persistent drug residue by sewage treatment effluents into the surface water.\(^{149}\) This example shows clearly the potential of multiresidue analysis of acidic pesticides as it is also applicable to the analysis of other polar contaminants such as drug residues. The drug clofibric acid and another polar contaminant N-(phenylsulfonyl)-sarcosine, also originating from sewage effluents, have been found unexpectedly in groundwater samples from the Berlin area during the monitoring of acidic pesticides!\(^{150–152}\) In 1994, both contaminants were also detected at concentrations of up to 270 ng L\(^{-1}\) in Berlin drinking water.\(^{153}\) The findings for clofibric acid in Berlin initiated many drug monitoring investigations. More than 40 pharmaceuticals have been found up to the microgram per liter level in surface water and a few even in groundwater samples.\(^{154,155}\)

The last example is that of DDA which was also found during the analysis of other acidic pesticides.\(^{156}\) The MID chromatogram in Figure 27 shows the detection of \(o,p'\)- and \(p,p'\)-DDA as their PFB esters in an extract of a groundwater sample from a bank filtration area. DDA is the long known polar metabolite of the non-polar insecticide DDT. Although it was known as one key metabolite in the biological degradation of DDT residues, it was never included in any monitoring program for DDT residues in the aquatic environment.\(^{157}\) Despite other DDT metabolites such as 2,2-bis(chlorophenyl)-1,1-dichloroethane (DDD), 2,2-bis(chlorophenyl)-1,1-dichloroethylene (DDE) or 2,2-bis(chlorophenyl)-1-chloroethylene (DDMU) it was neglected because it could not be analyzed together with the other non-polar DDT derivatives. DDA can, however, be analyzed together with other acidic pesticides in one multiresidue method. In recent investigations of Berlin groundwater and surface water samples it was found as the major DDT derivative in the surface water of a DDT Superfund site.\(^{157}\)

A review of analytical methods for phenyl and sulfonylurea herbicides is reported. Extraction from environmental samples can be carried out using different techniques like liquid–liquid partition, solid-phase extraction (SPE), microwave-assisted solvent extraction, and so on. Both herbicide classes are analyzed mainly using high-performance liquid chromatography (HPLC) coupled with a mass detector. Quantification limits are around the parts per billion level for many compounds. Multiresidue determination is easy for phenylurea compounds, but for sulfonylureas is limited by the different pKₐ values of the compounds.

1 INTRODUCTION

Phenylureas and sulfonylureas are two distinct classes of herbicide developed over different periods. Phenylureas were developed in the 1960s for use as soil-applied herbicides during the relatively short time interval between sowing the crop and its emergence. During this time the weeds are delicate and shallow-rooted and it is difficult to determine what proportion of a toxic dose of herbicide enters through the roots rather than the shoots.

In most members of the substituted urea herbicides, urea (1) is trisubstituted as phenylurea (2). One of the amino groups carries either two methyl groups or one methyl and one methoxy group. The other amino group is substituted with a benzene ring which, in most cases, contains halogen atoms.

In Table 1 some of the most common phenylurea herbicides are reported. Phenylureas are solids with a low vapor pressure ($10^{-6} - 10^{-8}$ mm Hg or $10^{-4} - 10^{-6}$ Pa) at room temperature and their aqueous solubility ranges from 4 to 700 mg L⁻¹.

Hassall classified ureas as herbicides that are mainly soil acting against seedling weeds and are inhibitors of photosynthesis. Some of the nonselective, preemergence and postemergence uses of phenylurea herbicides are listed in Table 2.

Urea herbicides in solution or suspension readily enter plant roots but the extent of translocation of different substances varies greatly. Chloroxuron and neburon tend to remain in the root system whereas monolinuron, fluometuron and metobromuron are largely translocated to the leaves. Once within leaves, some tend to stay near the leaf veins whereas others enter the mesophyll. Since movement is apoplastic, it is accelerated by factors that increase the rate of transpiration, including high temperatures, lower moisture and opening of stomata.

The principal mode of action of ureas is by disruption of the light reaction of photosynthesis, particularly by inhibition at one or both ends of photosystem II at the level of electron acceptor Q (quinone).

Sulfonylurea herbicides were developed in the mid-1970s for broad-spectrum weed control of a number of crops at very low use ratios (2–75 g active ingredient ha⁻¹). They have the advantage of good crop selectivity and very low acute and chronic animal toxicity.

The chemical structure of a generic sulfonylurea herbicide (3) is shown, while Table 3 reports some of the most common sulfonylurea herbicides.

Hassall classified sulfonylurea herbicides into those that act either at or before cell division.

The site at which the highly specific action of these herbicides is manifest is acetolactate synthase (ALS). This
are essentially the same, but there are differences in analyses. In both procedures the steps for determination of an analytical method, namely single and multiresidue

is the enzyme that catalyzes the first step in the synthesis of the branched-chain amino acids valine, leucine and isoleucine. The inhibition leads to the rapid cessation of plant cell division and growth.

Sulfonylurea herbicides are one of the most important classes of herbicides and their use is widespread owing to their selectivity towards a great variety of crops. A list of the uses and doses of the main sulfonylurea herbicides is reported in Table 4.

Analytical methods have been developed since the urea and sulfonylurea herbicides were first introduced. There are two distinct approaches to the development of an analytical method, namely single and multi-residue analyses. In both procedures the steps for determination are essentially the same, but there are differences in the solvents used for extraction and in the equipment. Differences were also observed in the dependence of the matrix by which the chemical must be extracted. The analysis of the two classes, urea and sulfonylurea herbicides, will be described separately.

2 PHENYLUREA HERBICIDES

Since the introduction of phenylurea herbicides, many analytical methods have been developed for their determination in water, soil and food samples. Initially, a direct gas-liquid chromatographic (GLC) analysis was used by a number of authors. Katz and Strusz\(^{(2)}\) report a gas chromatographic (GC) method for separation of several urea herbicides and their metabolites. The main drawback in using residue analytical procedures for the substituted urea herbicides was the long and tedious procedure required for qualitative identification and for quantitative measurements after alkaline hydrolysis to the corresponding aniline and the determination of the aniline either directly or as a halogenated derivative.\(^{(3-5)}\)

This was necessary because of the ease of thermal decomposition of many phenylurea herbicides. Using the programmed technique, separation of the parent compounds can be accomplished using a 1.2 m × 6.35 mm XE-60 column or under isothermal conditions at 130 °C using a 5% SE-30 liquid phase on Chromosorb® W 60 to 80 mesh solid support. The separation of parent herbicides under these conditions is illustrated in Table 5. With the programmed technique, separation of the parent compounds is almost identical. However, fenuron, linuron, chlorobromuron and monuron are easily separated while diuron is barely detectable. Neither neburon nor chloroxuron can be determined using the programmed technique. Under isothermal conditions, metobromuron and fluometuron were easily separated, and chloroxuron was easily distinguishable. Monuron, diuron and neburon all had a poor response and were essentially inseparable. The limit of detection (LOD) for the compounds was around 50 ng.

In the direct GC analysis, for good separations and reproducible analyses of such compounds, operational parameters must be rigidly controlled. Unfortunately,

During sample analysis such a restriction often makes direct determination impossible owing to unavoidable interferences. Direct alkylation of urea herbicides was first used in 1973(6) for sample analysis of urea herbicides. Lawrence and Laver(7) reported a GC method for the quantitative analysis of a number of urea herbicides (fluometuron, fenuron, monuron, linuron, diuron, chlorbromuron and chloroxuron) in selected foods (potatoes, carrots, oranges, peas, corn, pineapple, asparagus and spinach) by GLC after alkylation. The compounds were extracted from the crops with ethanol, which was subsequently partitioned between water and chloroform. The organic extract was evaporated to dryness and alkylated with sodium hydride–methyl iodide. The products were extracted with hexane and directly analyzed by GC using a Coulson conductivity detector in the nitrogen mode and a 2 m × 6 mm OD (outside diameter) coiled glass column packed with 4% SE 30/6% QF1 on Chromosorb® WHP (80–100 mesh). No column cleanup was required for any of the samples down to the 0.01 ppm level. Detection limits were about 0.005 ppm. Recoveries were usually 60–100% depending upon the herbicide.

Lawrence(8) reported a comparison of GLC and HPLC for the analysis of some herbicides in foods. This paper is noteworthy in that it is one of the first to propose detection of a urea herbicide (linuron) in foods as well by HPLC with a UV (ultraviolet) detector. Extraction was performed with acetone; extracts were partitioned into petroleum ether–methylene chloride, and cleaned up on a 2% deactivated Florisil® column.

Farrington et al.\(^9\) reported an HPLC analytical method for the determination of several phenylurea herbicides (chlorbromuron, chlortoluron, chloroxuron, diuron, linuron, metobromuron, monolinuron and monuron) in grain, soil and river water. The herbicides were extracted from grain and soil samples with methanol and from water samples with dichloromethane. Organic extracts were chromatographed on microparticulate silica bonded with octadecyltrichlorosilane using a mixture of methanol, water and ammonia as mobile phase. Recoveries were satisfactory; the lower recoveries from wheat may be attributable to residual oil, which remains after the evaporation of the dichloromethane, increasing the volume of the solvent, as this oil is miscible with methanol. The lower limits of detection were estimated to be 0.2 ppm for wheat and soil and 0.01 ppm for river water. Below these levels both coextractives and signal noise interfere.

Numerous HPLC methods for determining phenylurea herbicides in samples were later reported.\(^10\),\(^11\)

Over the years, analytical techniques have improved, especially concerning the sensitivity of the methods, which in the 1980s reached parts per billion and parts per trillion levels.

De Kok et al.\(^12\) described several chromatographic procedures for the determination of 15 phenylurea herbicides and their aniline degradation products. Analysis of the separate classes of compounds was achieved by reverse- and normal-phase HPLC followed by determination by capillary GC with an ECD. The anilines were formed by catalytic hydrolysis of the herbicides on silica columns (impregnated with 1 mmol g\(^{-1}\) of dimethylamine) and were derivatized with heptafluorobutyric anhydride for determination by GC with ECD (for nanogram levels of herbicides). A range of 14 heptafluorobutyramides could be separated on CP-Sil 5 fused-silica columns, with detection limits (by ECD) of almost 0.2 pg. These and other techniques can be combined as complete schemes for the analysis of mixtures of the herbicides and the corresponding anilines.

Luchtefeld\(^13\) reported an original method for the simultaneous determination of six phenylurea herbicides (chlorbromuron, chloroxuron, diuron, fluometuron, linuron and metobromuron) in eight different food products (asparagus, carrots, celery, corn, grapes, onions, potatoes, strawberries) by liquid chromatography (LC). The samples were extracted twice with methanol, by homogenizing the sample in the centrifuge bottle, and then centrifuging instead of filtering, so less sample manipulation was involved and solvent evaporation was minimized. The partition step was included to provide some cleanup as well as a means of transferring the residues to methylene chloride for further chromatographic cleanup. A single hexane extraction was sufficient to remove some oils that are found in products such as corn. Column
chromatography was included as a final cleanup prior to LC analysis. The Florisil® column was selected since it revealed no inconsistencies between batches. The extracts were analyzed using LC with postcolumn photodegradation, chemical derivatization with orthophthalaldehyde and spectrofluorometry. The LC procedure using postcolumn photolysis and chemical derivatization proved to be very selective for determining phenylurea herbicides in the presence of some food excipients which remain after partition and column cleanup. When UV detection alone was used, these excipients interfered with the analysis. Gradient elution was used to aid the separation of individual herbicides, to help separate any coextractives from herbicides and to remove coextractives from the column in each assay. Two mobile phase systems were used for the gradients: methanol–water (m-w) and acetonitrile–water (a-w). Recoveries were determined by spiking eight different food products with six phenylureas at 0.05 and 0.5 ppm. Average recovery at 0.05 ppm was 95% and at 0.5 ppm, was 98% ± 6.9. Table 6 reports the LOD and the LOQ for the six phenylureas. The LOD and LOQ were determined by calculating the amount of phenylurea required to give a response that was three times the baseline noise for LOD and ten times the baseline for LOQ. As indicated by the data in Table 6, the detection and quantification limits were lower for the mobile phase system of acetonitrile and water. The described LC procedure with gradient elution, postcolumn photolysis and chemical derivatization has resulted in an unprecedented selectivity for the analysis of phenylureas.

Kuehne et al. presented an analytical method for the determination of phenylurea herbicides in crops by column-switching HPLC, which allowed an improvement in residue analysis of phenylurea herbicides in terms of sensitivity. The method involves hydrolysis of a sample (5 g) of crops with aqueous NaOH for 6 h under reflux, partition of extract by steam distillation into hexane, partition into methanol–0.2 M HCl (33:67) and dilution with a mobile phase. Analysis was by column-switching HPLC on a column of Nucleosil® SA (10 μm), followed by a column of Nucleosil® C (10 μm), with methanol–aqueous phosphate buffer of pH 7 (33:67 and 3:2, respectively) as mobile phase (1 mL min⁻¹), and detection on the first column at 280 nm and on the second column at a vitreous carbon electrode at 0.9 V. Recoveries were 80–110% and detection limits were 0.02 mg kg⁻¹ for each herbicide.

Di Corcia and Marchetti presented a rapid and sensitive method for the determination of phenylurea herbicides in environmental aqueous samples by extraction with a Carbopack® cartridge followed by HPLC. The water sample is preconcentrated by passage at a flow rate of 150 mL min⁻¹ through a 250-mg graphitized carbon black (Carbopack® B) cartridge. After washing with 0.6 mL of methanol, the Carbopack® B trap is connected to a cartridge containing a strong cation exchanger. Organic matter trapped by the Carbopack® cartridge was eluted by passage of 6 mL of methylene chloride–methanol (95:5, v/v). Anilines and other basic compounds which can complicate the analysis of phenylureas were readsorbed on the exchanger from the methylene chloride–methanol mixture flowing through it, while the phenylureas passed through completely unrecovered. After evaporation and redisolution, the sample is subjected to reversed-phase gradient elution HPLC with a 25 cm × 4.6 mm ID (internal diameter) column filled with 5-μm LC-18 reversed-phase packing. The organic modifier was methanol–acetonitrile (85:15, v/v). Gradient elution of phenylureas was performed by linearly increasing the percentage of organic modifier from 47–70% in 20 min. It was shown that, in order to fractionate the 14 phenylureas considered, 15% acetonitrile in methanol gave the best results. Phenylureas were detected with the UV detector set at 250 nm. Recoveries of the phenylureas added to water at levels between 30 and 300 ng L⁻¹ were always over 92%. LOD (signal-to-noise ratio = 3) was estimated to be about 1 ng L⁻¹ for a 2-L sample. One of the advantages of the liquid–solid extraction (LSE) over liquid–liquid partitioning is that sampling and extraction of a water sample can be done simultaneously by passing the water through a sorbent trap as it is pumped at the sampling site. The small volume cartridge can then be transported to the laboratory for desorption and HPLC analysis.

Hatrik and Tekel reported a review of the methods for the determination of phenylurea herbicides, among other pesticide classes, in water samples. The introduction in the 1990s of new accessories for the classic HPLC (diode array detectors, microcolumns) has led to new efforts in the development of original analytical methods for the determination of phenylurea herbicides in samples.

Brandsteterova et al. described a method for the determination of linuron and monolinuron in milk samples using micro-HPLC. Milk (50 mL) spiked with linuron and monolinuron at 0.01–1 mg kg⁻¹, was mixed
with 50 mL of methanol and 10 mL of 0.1 M sodium acetate. After cooling in ice water for 10–15 min, the precipitate was filtered off and this process was repeated. The combined filtrates were extracted with CHCl₃ (3 x 30 mL) and the combined extracts were dried over Na₂SO₄ and concentrated to 2 mL at 40 °C. The residue was applied to a cartridge containing 3 g of Florisil® topped with 1 g of Na₂SO₄; elution was performed with 10 mL of CHCl₃. The eluate was evaporated to dryness and the residue was dissolved in 500 μL of methanol. The solution was filtered and the filtrate was analyzed by HPLC on a column (25 cm x 1 mm) of LiChrosorb® RP-18 (5 μm) with a mobile phase (60 μL min⁻¹) of aqueous 70% methanol and detection at 245 nm. Recoveries were 78.6–91.3% for linuron and 74.9–86.2% for monolinuron: the corresponding coefficients of variation were 0.8–1.8% and 0.7–1.2%.

Boussenadj et al. reported a method for the determination of phenylureas in water using microcolumn HPLC. Water (1 L) was mixed with 10 mL of 0.1 M sodium acetate, filtered and extracted with CH₂Cl₂ or CHCl₃ (3 × 50 mL). The combined extracts were dried using anhydrous Na₂SO₄ and evaporated to dryness at 40 °C. The residue was dissolved in 100 μL of methanol and a 0.2 μL portion of the solution was analyzed by HPLC on a column (30 cm x 1 mm) of Kromasil® C18 (100 Å; 5 μm) with a mobile phase (20–40 μL min⁻¹) of water–methanol (3:1, v/v) in 0.01 M LiClO₄ adjusted to pH 5.5 using 1% H₃PO₄, UV detection at 254 nm and electrochemical detection at 1.35 V vs Ag–AgCl. Under these conditions, UV detection was more sensitive for linuron, whereas electrochemical detection exhibited a higher sensitivity for metoxuron, diuron and neburon. The detection limit for each herbicide was 0.05 ng.

Lagana et al. reported a method for multiresidue analysis of phenylurea herbicides in crops by HPLC with diode array detector. Crops (20 g) were chopped and blended with 80 mL of methanol. The mixture was filtered and the filtrate was diluted to 100 mL with methanol. A 5-mL portion was passed through a LC-18 cartridge (6 cm x 8 mm) and the cartridge was washed with 5 mL of aqueous 80% methanol. This solution was diluted with 40 mL of H₂O and applied to a Carbopack® B cartridge (6 cm x 12 mm). The phenylureas were eluted with 6 mL of methanol–dichloromethane (1:19, v/v) and the eluate was evaporated under N₂ at 40 °C. The residue was dissolved in 250 μL of aqueous 40% methanol and a 50-μL portion was analyzed on a column (25 cm x 4.6 mm) of C1 (5 μm) equipped with a guard column (2 cm x 4.6 mm) of Supelguard® LC-18, with gradient elution (1.5 mL min⁻¹) with acetonitrile–methanol (3:17, v/v) in water and detection at 242 nm. Thirteen herbicides were separated using this approach. Recoveries of 0.05–0.2 ppm of each, added to nine different crops, ranged from 76 to 100%, with no interference from the matrix. The detection limit was 0.01 ppm. Confirmation of the identity of each phenylurea was obtained from complete spectra with a diode array detector.

The immunoassay technique has also been developed for analysis of phenylureas in environmental samples. Newsome and Collins presented the development of an ELISA (enzyme-linked immunosorbent assay) for urea herbicides in foods. Four hapten analogs to phenylurea herbicides were coupled to human serum albumin and ovalbumin in order to prepare immunogens and coating proteins, respectively. Antisera raised in rabbits immunized with three of the immunogens bound strongly to microtiter plates coated with a homologous hapten such that competitive assays were developed with the use of heterologous coating proteins. The specificity of the assays to 13 related compounds was studied. The N’-(4-chlorophenyl)-N-dimethylurea hapten system was used to determine monolinuron, diuron and linuron in foods. Methanol extracts (25 μL) were incubated at 4 °C for 30 min with antiserum diluted 1:4000 with bovine serum albumin, and 200-μL portions were added to microtiter plates which were then incubated for a further 15 min. The plate wells were emptied, washed and incubated at room temperature with a 1:1000 dilution of goat anti-rabbit IgG conjugate (210 μL). The wells were again emptied and washed, 210 μL of substrate (O-phenylenediamine dihydrochloric acid and H₂O₂ in citrate buffer) were added and after 20 min at room temperature, 2.5 M H₂SO₄ was added before optical density measurement at 492 nm. Satisfactory recoveries of monolinuron and diuron were obtained from food fortified at the 40–160 ng g⁻¹ and 0.25–2.0 μg g⁻¹ levels, respectively.

Schneider et al. described a highly sensitive and rapid ELISA for the phenylurea herbicides diuron, monuron and linuron. Antiserum, obtained from rabbits immunized with monuron–BSA conjugates which contained a C₃ or C₅ methylene group at terminal nitrogen were adsorbed on microtiter plates overnight at 4 °C in 0.5 M carbonate buffer of pH 9.6 and washed. Monuron, diuron and linuron samples (50 μL) and enzyme tracer (horseradish peroxidase–hapten conjugate; 50 μL) diluted in 0.2 M phosphate buffer in 8% saline, supplemented with 0.1% Tween 20 of pH 7.8 were incubated on the antibody-coated plate for 15 min. A 3,3’,5,5’-tetramethylbenzidine substrate solution (100 μL) was added, the reaction stopped after 15 min and absorbances were measured at 450 nm. Analyses were class or compound selective for individual herbicides dependent on the antisera used. Monuron, diuron and linuron demonstrated 50% inhibition values at 0.4, 0.5 and 0.8 μg L⁻¹ and detection limits of 0.04, 0.05 and
0.08 µg L⁻¹, respectively, in buffer. The method was applied to the analysis of water, orange juice and milk.

Katmeh et al.²² described a competitive ELISA for the determination of the phenylurea herbicide chlortoluron in water and biological fluids. Antibodies were raised in sheep against a \( N'-(3\text{-chloro-4-methylphenyl})-N\text{-methyl-N-carboxypropyl} \) urea/bovine thyroglobulin conjugate and the resulting antiserum was used in an ELISA for chlortoluron in natural and potable water and in plasma and urine. A microtiter plate was coated with 200 µL per well of the chlortoluron antibody diluted 8000-fold with 0.07 M sodium barbitone buffer of pH 9.6. After overnight incubation at 4 °C, 100 µL of the sample and 100 µL horseradish peroxidase-labeled chlortoluron, diluted 16 000-fold in PBS (phosphate buffered saline) containing 2.5% normal sheep serum, were added to each well and the plate was incubated for 1 h at 37 °C. Then, 200 µL chromagen substrate were added to each well. After a further 30-min incubation, the absorbance was measured at 450 nm. The calibration graph was linear up to 100 µg L⁻¹ of chlortoluron and the detection limit was 0.015 µg L⁻¹. The intra- and interassay RSDs (relative standard deviations) \((n = 6)\) were 2.6–6.8% and 6.9–14.6%, respectively. Recoveries of chlortoluron added to water and biological fluids were 78–127% and 87–113%, respectively.

Guihot et al.²³ reported the application of immunoasays for molinate and diuron herbicides to field water analysis. The two ELISA described can be carried out either on microwell plates in the laboratory or in polystyrene tubes in the field. Both assays are based on competition with a horseradish peroxidase conjugate of the herbicide for immobilized antibodies against the herbicide, although the assay for diuron requires prior coating of the plate or tube with protein A before coating with the antibody. The detection limits of the laboratory and field assays were 0.5 and 1 ppb for molinate and 0.02 and 0.15 ppb for diuron. There were no appreciable cross-reactions in the assays for molinate, but other phenylurea herbicides cross-reacted in the diuron assays.

Other work helps to present a complete overview of all analytical methods for phenylurea herbicides utilized through the 1980s and 1990s.²⁴–³⁹

3 SULFONYLUREA HERBICIDES

Owing to their thermal and chemical instability, the determination of sulfonlurea herbicides at low levels is very challenging and many different approaches have been reported. The earliest approaches utilized normal-phase LC with photoconductivity detection, however this detector has unacceptably long equilibration times. Sulfonylureas are not directly amenable to GC because of their extremely low volatility and thermal instability. Nevertheless, GC has been used in conjunction with diazomethane derivatization, pentafluorobenzyl bromide derivatization and hydrolysis followed by analysis of the aryI sulfonamides. These approaches have not been widely accepted, most likely because none of them perform well for the entire family of sulfonlureas, and while capillary electrophoresis has been evaluated for water and soil, the low injection volumes required may not yield the required sensitivity for certain applications. Enzyme immunoassay has been used for chlorsulfuron and triasulfuron, with LODs ranging from 20 to 100 ppt in soil and water. The most common approaches to sulfonlurea determinations currently involve reversed-phase HPLC with either UV or mass spectrometric (MS) detection. HPLC/MS has been used in conjunction with thermospray, fast-atom bombardment and direct liquid introduction. Electrospray and tandem mass spectrometry (MS/MS) have been combined.

The first sulfonlurea herbicide (chlorsulfuron (6), see Table 3) was introduced in 1982 and since then analytical methods for the determination of sulfonlurea herbicides in different matrices have appeared in journals worldwide.

3.1 Environmental Samples

Sulfonlurea analysis of both soil and water samples can be performed using quite different extraction and determination methods.

3.1.1 Extraction Techniques

Several methods have been proposed using liquid extraction for soil and water samples. Both matrices are extracted by modifying the pH of the medium and using different cleanup techniques. For chlorsulfuron determination in soil, samples were extracted⁴⁰ with aqueous 0.1 M Na₂CO₃–0.1 M NaHCO₃ (pH 10). The aqueous solution was washed three times with chloroform. Because the pKₐ of chlorsulfuron is about 3.8 the compound remained in the aqueous solution in its anionic form. The chloroform layers were then discarded. The pH of the aqueous solution was adjusted to 3–4 by adding 10% HCl and the solution was extracted three times with toluene and evaporated to dryness by adding 1% glacial acetic acid. The residue was dissolved in the mobile phase and purified in a silica Sep-PAK.⁸

Soil samples were extracted⁴¹ for nicosulfuron (11) and rimsulfuron (12) (see Table 3) determination by vortex mixing with aqueous 80% acetonitrile (Table 7). The extract was filtered and the filtrates were concentrated to a reduced volume with nitrogen and directly analyzed.

by a LC/MS (liquid chromatography/mass spectrometry) technique.

Tribenuron-methyl (15) was extracted (42) from 500-mL filtered sample of water on a C18 SPE column and cleaned up on a silica column. Chlorsulfuron (6), metsulfuron-methyl (8) and thifensulfuron-methyl (14) (see Table 3) were extracted and cleaned up similarly after pH adjustment of the sample to 4.5 with aqueous 8.5% H₃PO₄. Each extract was evaporated to dryness in a nitrogen stream and the residues were dissolved in 1 mL aqueous 10% acetonitrile. The method could be applied to other water types, e.g. ground, runoff and surface water.

An analytical screening method for the determination of nine sulfonylurea herbicides (see Table 8) in soil and water was reported by Powley and de-Bernard. (43) Fifty grams of soil were extracted with 100 mL of 80:20 (v/v) 0.1 M ammonium carbonate–acetone solution while 200 mL of water sample was directly extracted as indicated below. Soil extract and water samples were passed through a preconditioned 1 g C18 SPE cartridge. The pH of water samples was adjusted to 3.0–3.5 using dilute phosphoric acid. Elution was performed with 10 mL of 0.1% (v/v) glacial acetic acid in ethyl acetate. The eluates were evaporated down and reconstituted in ethyl acetate. After further passage through a 1 g silica SPE cartridge the sample was analyzed by HPLC. This method is not applicable to the determination of nicosulfuron (11) and rimsulfuron (12) (see Table 3) because these compounds are not quantitatively eluted from the silica cartridge.

Rodriguez and Orescan (44) analyzed 12 different compounds (see Table 9) in water samples using a similar approach. Water (250 mL) was treated with 2.5 mL of acetic acid and drawn through a preconditioned RP-102 SPE cartridge. Elution was performed with 10 mL of methanol and the eluate cleaned up using an anion-exchange cartridge (SAX) stacked on top of an alumina cartridge. The elution was performed with 17 mL of 0.5% acetic acid in dichloromethane with final suction. The final extracts were analyzed using electrospray LC/MS.

In another study (45) nicosulfuron (11), thifensulfuron-methyl (14), metsulfuron-methyl (8), sulmeturon-methyl, chlorsulfuron (6), bensulfuron-methyl (13), tribenuron-methyl (15) (see Table 3) and chlorimuron-methyl recovered from soils were dissolved in 100 µL 90% acetonitrile/5 mM ammonium acetate at pH 3.5 and a 10 µL sample was transferred to a Betasil C18 (5 µm) column (15 cm × 2 mm ID) with gradient elution (200 µL min⁻¹) with 90% acetonitrile/5 mM ammonium acetate. Chlorsulfuron (6), metsulfuron-methyl (8), thifensulfuron-methyl (14) and triasulfuron (9) at a concentration of 6 µg kg⁻¹ were extracted for 20 min from 20 g of soil using 120 mL of 0.1 M ammonium carbonate at pH 7. After centrifugation for 20 min, the supernatant

Table 9 Recovery results for 12 sulfonylurea herbicides in water. Fortification levels were 0.1–1.0 ppb (n = 17)

was acidified to pH 3–3.5 using dilute H₃PO₄ and applied to a SPE column. The herbicides were eluted with acidic ethyl acetate, dried at 40°C, reconstituted in methanol, agitated and mixed, evaporated to <0.4 mL and made up to 1 mL with aqueous 5% acetonitrile.

An SPE method based on polymeric sorbents was developed for the extraction of water and soil samples. SPE was performed on cartridges preconditioned with methanol and water. Water samples were adjusted to pH 3.5 with 10% H₃PO₄ before application. Elution was effected with dichloromethane. The eluent was dried over sodium sulfate, evaporated under nitrogen and dissolved in 30% acetonitrile in high-purity water.

Water was acidified to pH 3 ± 0.2 with anhydrous acetic acid, extracted by reversed-phase SPE eluted with methanol and cleaned up on a tandem system comprising a strong-anion exchange SPE cartridge stacked on an alumina SPE cartridge. The sample was eluted with 0.5% methylene acetic acid in dichloromethane, dried under nitrogen at 30°C and reconstituted with 0.05 M acetic acid. Water (1 L) was acidified to pH 2 with HCl, mixed with 5 mL methanol and subjected to SPE on Empore® C18 disks using ethyl acetate for elution. The eluate was dried over anhydrous sodium sulfate, evaporated under nitrogen and dissolved in 30% acetonitrile in high-purity water.

Table 8.

3.1.2 Determination Techniques

3.1.2.1 Liquid Chromatography Purified samples (40, 52) were analyzed by HPLC with a Du Pont Zorbax® SIL column (25 cm × 4.6 mm) set at 35°C and a photoconductivity detector. This detector is necessary in order to obtain adequate sensitivity and selectivity. A mercury lamp was used in the detector as it provided much greater sensitivity than a zinc lamp. Under these conditions, it was essential that the chromatographic system provided good temperature control of the column and reasonably pulse-free delivery of the mobile phase to minimize baseline fluctuations. Recoveries were measured on 16 spiked samples over a concentration range of 0.2–2.0 ppb for chlorsulfuron (6), rimsulfuron (12) (see Table 3) and sulfumeturon-methyl. An average value of 80% was found with a standard deviation of ±16%. Coupled with extraction, cleanup, and isolation procedures, the method provided a means of determining sulfonylureas in soil and water at levels as low as 200 pg g⁻¹ (0.2 ppb).

Powley and de-Bernard (43) report an analytical screening method for the determination of nine sulfonylurea herbicides in soil and water by LC with UV detection. The LOQs were 1 and 0.1 ppb in soil and water, respectively, for all herbicides. The samples were analyzed on a Zorbax® SB-Phenyl 4.6 mm × 250 mm column with gradient elution with acetonitrile, pH 2.7 phosphate buffer and pH 6.2 phosphate (1.5 mL min⁻¹) and UV detection at 245 mm. The soil and water recoveries are reported in Table 3.

Cinosulfuron (7), thifensulfuron-methyl (14), metsulfuron-methyl (8), sulfmeturon-methyl and chlorsulfuron (6) (50) (see Table 3) were analyzed by HPLC using a 2-μm Microsphere® C18 column (10 cm × 4.6 mm ID) operated at 35°C with methanol–0.1% phosphoric acid at pH 3 (9:11) as the mobile phase, an injection volume...
of 200 \mu L and UV detection at 226 nm. Linear calibration graphs were obtained for 5–250 \mu g L^{-1}. The recoveries of herbicides from freshly spiked soil samples and samples with aged residues at levels between 20 and 1000 \mu g kg^{-1} were between 70–100% with RSD between 1–10% (n = 4). The detection limits in soils were ~5 \mu g kg^{-1}.

LC was performed\(^{(47)}\) on a 5-\mu m waters symmetry C18 column (15 cm \times 3.9 mm ID) with gradient elution (1 mL min^{-1}) with 20 mM phosphate buffer of pH 3.4 (solvent A) and acetonitrile (solvent B) from 30% B (held for 4 min) to 80% B over 25 min and detection at 220–230 nm. The primary wavelength for quantification was 225 nm. For some analyses, tribenuron-methyl (15) and thifensulfuron-methyl (14) were also determined at 262 nm. Recoveries were >85% except for tribenuron-methyl (15) (75%) and detection limits were <100 ng L^{-1} for water samples.

Seven sulfonylurea herbicides,\(^{(49)}\) thifensulfuron-methyl (14), metsulfuron-methyl (8), triasulfuron (9), chlorsulfuron (6), rimsulfuron (12), bensulfuron-methyl (13) and tribenuron-methyl (15) (see Table 3) were analyzed by LC with UV detection and confirmatory analysis with an electrospray/mass detector. Volumes of 50\u00b5L were applied onto a 5-\mu m C18 column (25 cm \times 4.6 mm ID) with gradient elution (1 mL min^{-1}) with 3-mm acetic acid in acetonitrile or water (32–62\% A in 40 min) and UV detection at 230 nm. Detection limits depended on the particular herbicides and were 0.6–2 ng L^{-1} in drinking water (4-L sample), 2–9 ng L^{-1} in groundwater (2-L sample) and 13–40 ng L^{-1} in river water (0.2-L sample). The recoveries of 10–250 ng L^{-1} compound from various water samples were >94%. Confirmatory analysis of the isolated material was performed by LC/MS using the same chromatographic column. The MS data were collected using a time-scheduled three-ion SIM (selected ion monitoring) program. Detection limits for herbicides by LC/MS were 0.5–3 ng.

### 3.1.2.2 Liquid Chromatography/Mass Spectrometry

Applications involving the determination of sulfonylurea herbicides have included thermospray LC/MS techniques, which have shown a lower LOQ in the range of 20 ppb. Continuous-flow fast atom bombardment (CFAB) LC/MS techniques using packed capillaries have also been used. MS/MS techniques provide additional structural information as well as higher specificity than single mass analyzers equipped with mild ionized ion sources. All these techniques are described below for several sulfonylurea herbicides.

Reiser et al.\(^{(53)}\) proposed the application of microcolumn LC/CFAB/MS in environmental studies of sulfonylurea herbicides.

Shalaby et al.\(^{(41)}\) introduced the use of thermospray LC/MS for residue analysis of sulfonylurea herbicides and their degradation products. Thermospray LC/MS has emerged as a versatile and selective technique that offers chromatographic separation, positive structural confirmation, quantification and sensitivity, which meet the criteria for multiresidue methods, especially for water-soluble and polar pesticides such as sulfonylureas. The method has been developed for two sulfonylurea herbicides (nicosulfuron (11) and rimsulfuron (12)) and a major metabolite of each, involves a simple extraction scheme and requires no specific sample cleanup prior to chromatographic analysis. The sample solutions were analyzed by HPLC on a Whatman Partisil C8 column (25 cm \times 4.6 mm) with gradient elution (1 mL min^{-1}) with acetonitrile–0.1 M acetic acid followed by postcolumn addition of 0.5 M ammonium acetate buffer solution and thermospray ionization MS detection at m/z of 143–650. Recoveries for all compounds over four concentration levels are shown in Table 7. The average herbicide recovery was 88.3%, with an average standard deviation of 14.8% for the data population of 96 data points from 24 sample analysis. The LC/MS total ion chromatogram provides a typical profile of the soil studied and shows no interferences at the retention times for the four test compounds. The LC/MS ion chromatogram of a 0.02 ppm fortified soil, which is the lowest fortification level, showed good signal-to-noise ratio for the four test compounds at the method quantitation level.

Bosi et al.\(^{(42)}\) report an LC/MS method with an electrospray ionization interface to analyze four sulfonylurea herbicides: chlorsulfuron, metsulfuron-methyl, thifensulfuron-methyl and tribenuron-methyl. MS analysis was accomplished by SIM of the deprotonated molecular ion in negative-ion mode. The four compounds were quantitated with the external standard technique based on the integrated abundance of the molecular ion [M – H]^−. Good reproducibility and high sensitivity (detection limits for the four compounds were between 0.002 and 0.005 \mu g L^{-1}) were achieved. MS/MS in selected reaction monitoring mode on a characteristic product ion (m/z 139 for chlorsulfuron (6), metsulfuron-methyl (8), and thifensulfuron-methyl (14); m/z 153 for tribenuron-methyl (15)) was used as a confirmatory method. High sensitivity was also maintained with MS/MS, making it possible to identify sulfonylurea herbicides at very low concentrations.

Rodriguez and Orescan\(^{(44)}\) analyzed 12 different compounds in water samples using electrospray LC/MS on a Zorbax® RX-C8 (5 \mu m) column (25 cm \times 4.6 mm) fitted with a guard column (1.25 cm \times 4.6 mm) of the same material with gradient elution from 20% (held for 10 min) to 36.8% of acetonitrile in 0.15% acetic acid during the following 21 min and then to 50% (held for 12 min) in
1 min and electrospray MS detection with SIM. The limit of determination was 0.1 ng mL$^{-1}$ for all herbicides, and recoveries are reported in Table 9.

Determination of 18 acidic herbicides was studied with use of HPLC coupled via electrospray ionization with MS or MS/MS.$^{(54)}$ Analytes, chlorsulfuron (6), metsulfuron-methyl (8), thifensulfuron-methyl (14) and triasulfuron (9) were separated in a column (25 cm × 2 mm ID) of Hypersil® BDS C18 (5 μm). The gradient mobile phase (0.2 mL min$^{-1}$) contained 1 part acetic acid in 900 parts of methanol–H$_2$O (1:9 to 100:0 in 45 min). The electrospray voltage was 5 kV at a temperature of 250°C and in both MS and MS/MS. SIM was from m/z 50 upwards. For the latter the collision gas was Ar at 1 mTorr and 10–30 eV. Detection limits using MS in the SIM mode were generally 0.4–0.5 μg L$^{-1}$, whereas detection limits were ten times higher using MS/MS detection.

Chlorsulfuron (6), metsulfuron-methyl (8), thifensulfuron-methyl (14) and triasulfuron (9)$^{(6)}$ were analyzed on a 5-μm ODS Hypersil® column (10 cm × 2.1 mm ID) with gradient elution (0.2 mL min$^{-1}$) with 10–80% formic acid (0.1%)/acetonitrile over 28 min and SIM/MS detection. Calibration was carried out at four concentrations over 15–170 μg mL$^{-1}$. The detection limit was <0.1 μg kg$^{-1}$ and recoveries were 80–100%.

Li et al.$^{(45)}$ reported a determination using a triple quadrupole mass spectrometer operated in positive ion mode, via an ion spray under SIM conditions. The nebulization gas (60 psi or 413 700 Pa) was nitrogen and the curtain gas was (1.2 L min$^{-1}$) nitrogen. The collision gas, argon, was set at an approximate collision thickness of 250 × 10$^{12}$ atoms cm$^{-2}$. Calibration graphs were linear for 0.05–10 ppb of each sulfonated aza. Suggested acceptance criteria for forensically valid data include a HPLC retention time reproducibility of ±2% and the selection of at least two and preferably three precursor product ions and an absolute abundance of ±20% for selected ions.

3.1.2.3 Capillary Electrophoresis Chlorsulfuron (6), chlorimuron and metsulfuron$^{(55)}$ were analyzed using the capillary electrophoresis technique with an apparatus equipped with an untreated fused-silica capillary (50 cm effective length × 2 mm ID) operated at 25 kV and 35°C. The electrolyte buffer was 30 mM sodium borate/80 mM SDS (sodium dodecyl sulfate) containing 14% aqueous methanol/20% aqueous isopropanol at pH 7 and detection was at 214 nm. The peak area was used for the quantitation of chlorsulfuron (6), metsulfuron and chlorimuron. Calibration graphs were linear from 0.6–10 ppm of sulfonylurea herbicides with detection limits of 0.63 ppm for chlorimuron and 0.5 ppm for metsulfuron and chlorsulfuron (6). Inter- and intraday RSDs (n = 10) were ≤4% and ≤2.4%, respectively. The mean overall recovery for the three herbicides was 95.4 ± 16.1%. For concentrations < 10 ppb the concentration was a limiting factor and HPLC was easier and more accurate than micellar electrokinetic capillary chromatography (MECC). Metabolites$^{(56)}$ of eight sulfonylurea herbicides (chlorsulfuron (6), bensulfuron-methyl (13), tribenuron, triasulfuron, ethamsulfuron, rimsulfuron, chlorimuron and metsulfuron methyl (8)) in aqueous solution were separated using the same apparatus. The only difference was the running buffer of 50 mM sodium borate/22 mM SDS/10% methanol at pH 8.

Capillary electrophoresis$^{(48)}$ was performed on a column (122 cm × 75 μm ID; effective length 100 cm) operated at 30°C and 30 kV with a running buffer of 50 mM ammonium acetate of pH 4.75 in 12% acetonitrile and detection at 240 nm. LC was performed on a 5 μm Zorbax® RX-C8 column (15 cm × 2.7 mm ID) with gradient elution (0.25 mL min$^{-1}$) with acetonitrile/acetate and electrospray MS detection using a time-scheduled SIM (positive mode) of the M + H ions for each compound. The method was used to determine 12 sulfonylurea herbicides in water. Detection limits for LC/MS ranged from 0.01–0.12 ppb.

Bensulfuron-methyl (13), sulmefuron-methyl, nicosulfuron (11), chlorimuron-ethyl, thifensulfuron-methyl (14), metsulfuron and chlorsulfuron (6)$^{(57)}$ were separated, in the order cited, in a 57 cm × 75 μm ID capillary (effective length 50 cm) at 30 kV with (50 mM ammonium acetate buffer of pH 5.0)–acetonitrile (3:1) as running buffer and detection at 214 nm. On-column detection limits were 80–100 fM (injection volume 20 nL).

3.1.2.4 Gas Chromatography Thermally stable N,N'-dimethyl derivatives$^{(58)}$ for the GC analysis of chlorsulfuron (6) in Table 3 and metsulfuron-methyl (8) in Table 3, both model sulfonylurea herbicides, were produced by methylation of a 1 mL sample in ethyl acetate with 0.5 mL of diazomethane/ethyl acetate for 30 min. The solvent was evaporated under nitrogen and the residue was dissolved in 1 mL of toluene for GC analysis on a column (25 m × 0.2 mm ID) coated with HP-5 (0.33 μm) with temperature programming from 85°C (held for 1 min) to 150°C (held for 2 min) at 40°C min$^{-1}$, then to 250°C (held for 20 min) at 5°C min$^{-1}$ and ECD or nitrogen-phosphorus (N-P) detection. Peak identification was confirmed by GC/MS. The RSD were ≤3% and the calibration graphs were linear for 0.1–10 μg mL$^{-1}$ (6) and (8) in Table 3. The detection limits were 50 and 100 pg for (6) and (8) in Table 3, respectively. Quantification limits were <0.1 μg L$^{-1}$ for water and <1 μg kg$^{-1}$ for soil. Recoveries in water were 94–120% and 84–114% for (6) and (8) in Table 3, respectively, with an RSD of 2–15%. The corresponding recoveries for soil were 59–104% and 65–121% (RSD 8–21%).
Crop determination has been reported only by Krynis-
tsky and Swineford. Grain samples were extracted
with acetonitrile and partitioned with hexane. The
combined acetonitrile layers were evaporated to dry-
ness at 40°C and the residue was dissolved in 0.05 M
citric acid with sonicating. The resulting solution was
cleaned up on an Isolute 5 CX cartridge. The sul-
fonylureas were eluted with 0.1 M ammonium acetate.
The sample was collected and extracted with acetoni-
trile–CH2Cl2 (1 : 19, v/v). The organic extract was ana-
yzed using a Model 270A-Ht instrument equipped
with a fused-silica capillary (90 cm × 75 µm ID; 68 cm
to detector) operated at 35°C with an applied potential
of 25 kV and UV detection. The running buffer com-
prised 50 mM SDS/25 mM NaH2PO4 adjusted to pH 6.15
with 25 mM Na2HPO4. The lower detection limit was
~0.02 ppm, except for rimsulfuron (12) and tribenuron-
methyl (15) (0.035 ppm) (see Table 3). Recoveries were
72.9–118.5%.

3.1.2.5 Enzyme Immunoassay Kelley et al. proposed a method for determination of chlorsulfuron (6)
(see Table 3) in soil by enzyme immunoassay. They
describe ELISA, a sensitive immunological technique
that can monitor nanogram quantities of chlorsulfuron
(6) in crude soil extracts. The ELISA technique is
based on the ability of animals to produce highly
specific antibodies to foreign materials. Antibody is
collected from rabbit serum and becomes one reagent
in a rapid solid-phase assay that is both specific and
sensitive. The assay detects other sulfonylurea herbi-
cides, which are chemically similar to chlorsulfuron
(6), but it fails to detect sulfonylurea with different
chemical structures. The detection limit in soil was
0.4 ppb.

Other work helps to present a complete overview of
all analytical methods for sulfonylurea herbicides utilized
through the 1990s,

For pesticide residue determination, field sampling and analysis of agricultural soils and sediments requires the consideration of several seemingly interrelated factors. The mechanisms by which pesticides are adsorbed, absorbed, and desorbed from soils are not well understood for most families of chemicals or for most soils. In addition, soil properties are both spatially and temporally variable, so that the question of sampling methodology becomes important in order to insure that the samples taken are statistically representative of the larger population being examined. Thus, the investigator must weigh the attributes and limitations of each and then choose the best overall compromise among sample size and numbers, analyte specificity, and experimental designs. Following proper collection, the laboratory analyst must then choose among several options for selective extraction techniques for removal of the pesticide analytes of interest. For most applications, one of the following will be used: a classical approach employing a suitable solvent or cosolvent mixture in either a batch shake-out or Soxhlet extraction apparatus. Other more recently developed options include the use of extractant solvents or cosolvent mixtures held under elevated pressures and temperatures (pressurized fluid extraction (PFE)) or pure substances amended with cosolvent modifiers and held above their respective critical points (CPs) (supercritical fluid extraction (SFE)). Another option is the use of ultrasonic energy (sonication) to facilitate extraction. Each of these approaches relies upon an input of sufficient kinetic energy from an externally applied source to the sample slurried with extractant. As the binding energies responsible for the retention of pesticides on soil are overcome, sorbed solutes are released into the solution phase. Studies which address pesticide fate issues often also require determination of soil metabolite and degradate compounds along with the registered parent chemical. For many families of insecticides and herbicides, these same extraction protocols can be used to quantitatively remove the major daughter compounds from soils without requiring an additional extraction step.

1 INTRODUCTION

Soil is the basis of mankind's interactions with his environment because it is the interface between aquatic, atmospheric, and terrestrial ecosystems. Man’s ability to manage soil for food and fiber production is a principal tool in combating global hunger and avoiding starvation. On many soils around the world food and fiber production is increased by the effective use of agricultural chemicals to combat a host of yield-reducing pests which attack or compete with crops and/or invade the soil volume. Beginning about 50 years ago,
numerous chemicals have been developed and marketed to farmers for the purpose of mitigating or eliminating pests, primarily insects, weeds, and fungi, which are responsible for reducing both the quality and quantity of harvested crops.

The use of pesticides to maximize crop production has grown steadily over four decades and the development and registration of new chemicals is continuing. In many areas of the world today it is common practice for producers to use combinations of chemicals on each field to control a variety of insects and weeds, either as a preplanting, at planting, or post-emergence application, all applied directly upon or into the soil. These farming operations, while producing a more abundant and higher quality food supply, also carry several unintended and potentially undesirable environmental consequences. For years many public and private institutions and agencies have sponsored research on the environmental fate and transport of the chemical legacy of pesticides used in agricultural production. As a result, it is now apparent that long term use also yields several unintended outcomes. These include contamination of surface water (via runoff) and shallow groundwater (via soil profile leaching) resources in many areas, and diminished air quality wherever farming operations are conducted (via volatilization from plant and/or soil surfaces). Scientists studying soils have also suggested that the effects of long term usage of pesticides may also include diminished soil fertility resulting from reduced or unintended shift in biodiversity within soil microorganism and macrofauna populations. Since pesticides are very often applied directly to soils it then becomes imperative to sample and analyze these materials when studying the environmental impacts of farming systems. If the goal is to quantify environmental water quality end-points, then some systematic soil sampling should be conducted parallel with the obligatory water sampling.

The purpose of any soil sample is to obtain information about a particular soil. The sample itself virtually is never the entire soil volume in which the investigator is interested. Therefore, this information from the sample is of interest only insofar as it provides information concerning the larger soil volume. For any soil sample, there are certain properties which describe it. In the broadest context, the purpose of sampling and analysis is to estimate these characteristics with an accuracy which will meet the data needs at the lowest cost. Sampling and analysis of agricultural soils following pesticide applications is a powerful tool through which to gain insight into the nature of the processes which result in both target pest control and potential environmental pollution. Soil sampling and analysis for pesticide content effectively supports many research goals including:

- Enhanced understanding of the cause-and-effect relationship between pesticide use for agricultural production at a given locale and observation of pesticide contamination of the surrounding environment.
- Enhanced understanding of the issues attendant to efficacy of the selected pesticide in controlling intended target pests and how soil properties and conditions might influence the response for a particular chemical.
- Delineation of the microbiological transformation processes which govern the environmental legacy in the soil for each pesticide.
- Support of transformation and transport studies in the field by delineation of soil residence time (half-life) for the parent chemical or family of chemicals within a soil series or combinations of materials.
- Experimental determination of soil affinity coefficients normalized for a soil series or to specific soil properties and useful to modellers as input parameters for model validation as well as pesticide transport simulations.
- Determination of specific potential for ‘leaching to groundwater’ by examination of the concentration gradient throughout the soil profile by analysis of small increments cut from continuous cores.
- Determination of surface loading from application in order to estimate losses to the atmosphere through volatilization from soil surfaces.
- Evaluation of agricultural soil as a test matrix for analytical chemistry applications; e.g. development of residue methods for new chemicals or for improvements of existing methods or for standardizing techniques against authentic reference materials.

2 THE OCCURRENCE OF PESTICIDE RESIDUES IN SOILS AND SEDIMENT

Soil is a complex living dynamic assemblage of organic and inorganic chemical components. The mineral matrix for most soils is a complex assembly of layered 2:1 phyllosilicate minerals bound together with interlayer metal bridges, most notably aluminum, iron, or manganese. Organic matter in soil is best viewed as a mixture of organic compounds which (a) vary in molecular weight from small monomeric electrolytes [such as the hexose monosaccharide glucose] to very large polysaccharide electrolytes [such as plant starches or bacterial dextrans], (b) vary in stereochemistry and/or configuration, (c) vary widely in the functionality imposed upon both aliphatic and aromatic carbon skeletons, (d) vary greatly in their potential for electrostatic interactions,
and (e) lack the regularity of structure characteristic of many biopolymers, such as proteins, nucleic acids, and polysaccharides. Adsorption–desorption plays a paramount role in each physical process affecting the behavior of residues in soil. Pesticides are adsorbed by soil organic matter as well as by inorganic soil fractions, and the relationship between adsorption at both possible sites depends upon the specific properties of the soil (sorbent) and the pesticide (sorbate). Retention does not occur by a single mechanism, but rather is best described by a continuum of interactions. In general, binding energies for pesticide–soil associations fall within the 2–10 kcal mole range (van der Waals forces), much weaker than 50–100 kcal mole$^{-1}$ range for covalent bonds. This relatively weak interaction makes possible the extraction of residues by the techniques described herein.

As a class of commercially important synthetic chemicals, pesticides have come under scrutiny due to their wide-spread distribution throughout our terrestrial environment. Today more than 30 classes of chemicals with pesticidal properties are now widely acknowledged by most scientists and regulators, alike. Illustrating this diversity are the variety of chemicals registered for a broad spectrum of problems in weed, insect, and fungal control (Table 1). Nearly all of these chemicals represent post-World War II developments occurring in the last forty years.

Globally, the development of chemicals for control of weeds has proceeded much more rapidly than for other families of chemicals targeting insects, fungi, or other types of pests. In recent years, herbicides have accounted for approximately two-thirds of the global market for synthetic organic pesticides.

The nature of the association of a specific pesticide to a specific soil surface is largely governed by the interactions between functional groups. The major functional groups on inorganic surfaces which contribute to the adsorptive reactivity of pesticides are siloxane ditrigonal cavities contained in phyllosilicate clays and inorganic hydroxyl groups generally associated with metal (hydrous) oxides. Siloxane cavities are Lewis bases which create a net negative charge. Inorganic hydroxyl groups are the most abundant and reactive functional groups found on soil clays and are associated with the surfaces. Their specific reactivity varies depending upon both the number and type of coordination to metal ions. Soil organic matter includes polymeric organic materials, decomposing plant and animal residues, and soil microorganisms. A wide variety of functional groups are represented by the humic substances of soil. While the exact structure of humic substances remains elusive, most researchers agree that among its component chemical-types are large aromatic polymers composed of N-heterocycles, quinones, phenols, and benzoic acid derivatives. Recent studies employing infrared and magnetic resonance spectroscopic techniques have also identified carboxyl, carbonyl, phenylhydroxyl, amino, imidazole, sulfhydryl, and sulfonic acid functionality in soil humic materials. Soil humic materials also contain relatively high concentrations of stable free-radicals. The variety of functional groups identified in soil organic fractions along with the sterically and electrostatically controlled interactions between them results in a complex and continuous range of reactivities of soil organic matter toward pesticides. Thus, for any given pesticide, an increase in its polarity, number of functional groups, and ionic nature will all increase the number of potential adsorption mechanisms for that chemical. This is illustrated for the triazine herbicides, in which it has been postulated that van der Waals forces, charge transfer complexes, hydrophobic bonding, cation exchange, and cation bridging, all play a significant role in binding to soil.

information deemed necessary for successful completion of the project should be assembled prior to the start of any experiments.

Second, a clear definition of what constitutes the variables characteristic of the population to be sampled across the field site. The selection of technique for determination is dictated by both the data requirements implied by the objective and the requisite minimal level of detection necessary for each analyte. As an example, for the location-in-space spatial aspect of soil sampling, is centimeter accuracy or minute of angle in latitude and longitude accuracy in the X and Y coordinate axes sufficient, and over what range or distance? For the chemical analysis aspect of soil sampling, what is the optimum sample size to be taken relevant to the minimum detection limit for the analytical method selected? Is a 50-g sample sufficient to achieve a chromatographic instrumental response distinguishable above background on an injection equivalent to 20 pg of pesticide analyte, or is a 2 kg sample required? Typically, in processing soil for pesticide residue determination, analysts have alternative means for adjusting instrumental responses for sample extracts which do not fall within the expected normal ranges. These include phase transfer, concentration, or dilution with solvent.

Third, the selection of an appropriate sampling plan designed in consultation with a skilled statistician is essential. Effective and thorough sampling regimes which indicate how many observations are necessary and at which points samples need to be taken can be categorized in two types. Classical, or design-based, sampling aims at estimating how much pesticide contamination is present. Alternatively, the geostatistical, or model-based, sampling aims to predict as accurately as possible where the contamination is present. In classical systematic sampling, sample units are selected at some equally spaced interval, resulting in a uniform distribution of observations over the entire population. Shortcomings to this approach lie in statistical probability in that not all locations within the population have an equal or a chance of being sampled. Simple random sampling tends to undersample small, but potentially important, locations within the population. In the combination of the two approaches, random systematic sampling, the locations within the population are arranged in some order, the first sample then randomly taken, and each subsequent sample then taken around that first sample using some fixed interval. Stratified random systematic sampling allocates elements of the population into sub-populations based upon some chemical or physical property of the soil prior to sampling, then each stratum is randomly sampled.

Strata criteria might be based upon soil classification, slope of the terrain, or erosional class. This approach is considered to be the best option for geostatistical treatment of data because it avoids the possibility of bias resulting from periodicity in sampling locations. Any test of the reliability of spatially distributed data requires assumptions regarding that distribution. Several researchers have criticized the use of classical statistics for treatment of spatially-distributed data, arguing that the conclusions are based upon assumptions not necessarily valid for spatially-dependent variables. The practice of using only a few sampling locations to characterize a spatially complex study area can be a major source error in spatial statistics. This issue is extensively discussed by Uehara et al., Lascano and Hatfield, and Curran and Williamson. Furthermore, many other sampling regimes exist.

Fourth, implementation of the survey with set procedures and protocols. All sample properties ancillary to the pesticide content and relevant to the objective must be sampled and determined as well and none should be omitted due to cost constraints. If necessary, fewer sampling sites is the best way to accommodate costs. The essential statistical support should be dictated by the sampling objective. Spatial uncertainty in the data is a consequence of taking an unnecessarily limited number of observations, and it can be avoided by taking more samples. Non-spatial uncertainty, such as that resulting from measurement error, can be reduced by repition of the measurement or by increasing the accuracy of the measurement system. No two locations in any soil sampling regime are both temporally and spatially identical; therefore, a temporal variability experiment must be conducted in parallel time blocks in order for environmental data comparisons to be valid.

Fifth, performing an appropriate analysis(ses) with the given data. Visualization of pesticide residue data in three-dimensional formats is necessary to clearly observe the distribution of results. The extent of the distribution of pesticide concentrations is best presented in the context of soil volume data. In addition, linking the data to hydrologic models can provide insight into the mobility of pesticidal compounds through the soil volume. A geostatistically based multidimensional visualization tool should be used to estimate and display the error or uncertainty associated with the spatial data. The use of the ‘fill-in’ tools, kriging or weighting, for estimating non-measured values by smoothing areas between sampled locations should be approached with caution, as they frequently can be taken to overrepresent the sampled information.

Depending upon the data requirements, a substantial saving of laboratory resources can be achieved through compositing of samples. A number of field samples are
thoroughly mixed to form a composite which is then subsampled for analysis. Composite sampling can be used in conjunction with stratification wherein each field unit is sampled and composited separately by stratum where it is known that the variabilities within the stratum are inconsequential. However, compositing of samples may result in a loss of spatial and temporal resolution of information.

Soil samples taken for pesticide analysis should be immediately placed in glass or Teflon® containers and sealed under screw-cap such that headspace is minimized. For pesticide determinations which commence with extraction, it is essential that samples be refrigerated as soon as possible, maintained under refrigeration until analysis, and analyzed as soon as possible. The most frequent changes in composition of soil samples during the time between collection and extraction are loss of volatile constituents, or biodegradation, oxidation or reduction of the specific pesticide residues of interest. Low temperatures reduce biodegradation and loss of volatile constituents, but freezing of water-containing samples can result in profound changes in the physical and/or chemical composition. Soil samples pulled from anaerobic zones must not be exposed to air. Typically, soil samples taken for pesticide extraction are not air-dried, nor are they ground to uniform particle size, nor are they screened or sieved, as is frequently done for determination of inorganic constituents, especially total elemental composition. Instead, a representative small portion of the thoroughly mixed bulk sample is taken for moisture determination and that value is then used to calculate a dry weight equivalent for the soil at its field moisture content. In the example, Equation (1) is used in the final calculation to compute analyte concentrations back to a dry-weight basis, and Equation (2) for calculating percent moisture in soil.

\[
\text{Wt, dry} = \frac{\text{Wt, wet}}{1 - \frac{\%\text{Moisture}}{100}} \quad (1)
\]

\[
\%\text{Moisture} = 100 \frac{\text{Wt, wet} - \text{Wt, dry}}{\text{Wt, wet}} \quad (2)
\]

4 GENERAL CONSIDERATIONS FOR EXTRACTION

In order to extract a pesticide residue from a soil matrix and into an organic solvent phase, several interactions must be overcome and replaced with alternative interactions. The hydrogen bonding, van der Waals, and dipolar interactions between the pesticide molecule and its neighboring pesticide molecules and/or solvent molecules must be broken. The energy required to break these interactions generally increases with increasing polarity of the pesticide molecule. Once the pesticide is released from the matrix, it must be solubilized into the liquid solvent, which requires the breaking of interactions between solvent molecules. This can result from (a) weakening of the solvent–solvent molecule interactions so that they wet the soil surface sufficiently to disrupt the pesticide–soil interactions, or (b) weakening the solvent molecule network sufficiently to allow the pesticide to be accommodated into the solvent molecule environment. For polar solvents commonly used for extractions, the energy associated with this is larger than for less polar solvents, and can be estimated from surface tension and boiling point data alone.

Once solubilized into the solvent, the pesticide is enjoined into new interactions with solvent molecules as a stable solvent–molecule cage is formed. The stability of this interaction results in the release of binding energy, which is largest when the interaction of the pesticide and solvent is a more polar interaction. In order to achieve the maximum solubility in the shortest time, the energy barriers to solvation must be overcome. Increasing the temperature will result in increased rates for the interactions necessary for extraction to occur. Higher temperatures decrease hydrogen-bonding and dipolar interactions occurring on the relatively high energy surfaces of the soil. In addition, thermal energy reduces both surface tension and viscosity of the solvent, thereby enhancing diffusion. Heat will also disrupt stable lattice structures of the soil and impart a degree of kinetic energy to the pesticides. It will also decrease surface tension of the solvent and enhance diffusion. This results in a general decrease in solvent–solvent interactions, thereby accommodating pesticide molecules more easily into the solvent environment.

In analytical applications of soil extraction for pesticide residues, one important indicator characteristic for each chemical is its net molecular polarity. For most nonionic pesticides, polarity can be estimated from water solubility data. While pesticide association with soils material is mechanistically very complex, a useful rule-of-thumb for analysts choosing one among several extraction techniques is that water solubility and the soil-affinity coefficient usually enjoy an inverse relationship. The more strongly bound to soil are the pesticides, the more nonpolar and insoluble they appear to behave. Generally, more polar pesticides are best extracted from soil with more polar solvents or solvent mixtures. Table 2 presents water solubility range data for the most common families of herbicides, insecticides, and fungicides. Only the backbone structures which define the family are shown, as the specific substitution pattern for each chemical will also exert a great influence on extraction efficiency. Numerous resource materials are available which provide this type of information. The most widely used are the *Farm Chemicals Handbook*, updated annually and distributed by the Meister Publishing Co., Willoughby, Ohio; the

\(^a\) Water solubility, mg L\(^{-1}\), at 293–298 K.
Classical methods for extraction of pesticides from soils and sediment materials generally involve the use of a solvent selected because of its optimum solubility with respect to the analyte(s) and its minimum solubility with respect to the sample matrix. In the simplest application, solvent is added to the soil sample while it is agitated to allow the analytes to dissolve into the surrounding liquid until all have been removed. This technique works well when the analyte(s) of interest are very soluble and the sample matrix is in a finely-divided and uniform physical state, or is very porous, thereby permitting closer association between solvent and solute molecules. When better contact between analyte and solvent is required, additional steps can be taken to insure maximum removal. The most popular of these for pesticide residue extractions are additional heating, additional pressure, and sonication, all of which require application of externally-applied forces to the soil–solvent mixture.

6 SOXHLET EXTRACTION AND SOLVENT-SHAKE EXTRACTION

6.1 Principle

Traditionally, solvent extraction has been the most widely used approach to removal of pesticides from soils. Techniques range from simple batch extractions using mechanical shakers to sophisticated devices which continuously recycle extracting solvent. By far the most widely used apparatus is the Soxhlet extractor (Figure 1). It was conceived and developed by German chemist Franz von Soxhlet (1848–1913) more than 100 years ago. In this device a soil sample is contained in a thimble of some porous fiber composition and positioned over a boiling solvent. More recently, glass extraction thimbles with fritted disk sealed in the base have become popular for soil–pesticide extractions. Any desired volatile solvent may be used, either water-miscible or water-immiscible. The solvent is heating to boiling, where it vaporizes. When it condenses, it drops onto the soil contained in the thimble, and extracts soluble compounds. When the liquid level fills the body of the extractor, the solvent containing the extracted pesticide is automatically siphoned back into the boiling solvent. After many cycles and many hours, the solvent is evaporated, leaving a residue for either further purification treatment or direct instrumental analysis. Over the years several modifications have been described, the best known being the Goldfisch technique. In this procedure, the
condensed solvent is allowed to drip into and through the sample thimble, immediately returning to the boiling solvent. It has no filling and siphoning action as in the original Soxhlet apparatus. Soxhlet extraction is simple, effective, and relatively inexpensive, other than the costs of solvent disposal. For many pesticides, it provides good analyte recovery. However, its traditional operation is slow and it requires large volumes of solvents. While extractions may last for 24 hours or more, they require very little user intervention once the process has begun. Small-volume Soxhlet systems are available, but the sample size often is dictated by the pesticide residue concentration, the minimum mass of analyte necessary for a representative sampling, and the chromatographic technique chosen for the determination. All of these often combine to require a larger soil sample size.

Through the years and through many improvements the original Soxhlet techniques remained time-consuming and prone to variability. By the mid-1970s a new accelerated solvent extraction (ASE) technique was described which reduced extraction time to as little as 30 min. Known as the Randall\(^\text{11}\) modification, the sample thimble is totally immersed in the boiling solvent. The underlying principle is that the pesticide residue to be extracted is more soluble in hot solvent than in cold solvent at room temperature. This method has become the basis for many commercial automated solvent extraction systems derived from the original Soxhlet. Its limitations notwithstanding, Soxhlet remains the most exhaustive option available to the analyst.

### 6.2 Applications

Table 3 compares extraction efficiency, as determined by percent recovery, for a series of representative CHIs spiked onto clay samples for both conventional Soxhlet and automated Soxhlet techniques.\(^\text{12}\) In every case, the Randall technique yields higher recoveries in a fraction of the time. While these data apply only to the nonpolar, very hydrophobic, low water-solubility insecticides, similar results are obtained with many classes of herbicides, including chlorophenoxy acids, triazines, chloroacetamides, and dinitroanilines. In recent years, automated extraction techniques have gained global acceptance as well as regulatory approval from the United States Environmental Protection Agency (USEPA). An exemplary USEPA approach can be found in the solid waste series, SW-846. Method 3541 describes the extraction of organic analytes, including many pesticides, from soil, sludge, and sediment by automated solvent extraction.\(^\text{13}\) In addition to semivolatile organic compounds, which includes most pesticides, this method is applicable to polychlorinated biphenyls (PCBs) as well.

### 6.3 Advantages

Modern automated Soxhlet extraction offers several benefits over more traditional systems. The Randall boiling

step accelerates the extraction three- to five-fold over conventional Soxhlet. Automated systems allow users to extract multiple samples simultaneously, thereby saving time and money. For many pesticides, especially hydrophobic nonpolar compounds, repeatability of recovery and efficiency are improved, often by more than 20%. Commercially available extractors use less solvent than conventional systems, require less fume hood space, and include built-in safety features with mechanisms designed to minimize unsafe operations.

The traditional Soxhlet procedure also offers several benefits for some users. It is often the method of choice for smaller laboratories due to its relatively modest capital investment. In addition, USEPA considers it to be the exhaustive extraction technique for removal of organic compounds from solid matrices, so that it has become the de facto benchmark for comparisons.\(^\text{[14]}\)

Many of the newest generation of herbicides and insecticides are nonionic, very polar, and highly water soluble. Consequently their residues are easily removed from cultivated soils merely by contact with various aqueous solutions. Such is the case for the SU metsulfuron-methyl (CAS #74223-64-6), which is readily extracted from cultivated soils by frequent shaking of a slurry with a dilute solution of PBS, (phosphate buffered saline) solution for 30 minutes. Following centrifugation, the aqueous extract is acidified to pH = 3, and the metsulfuron extracted by SPE on polymeric-resin cartridges.\(^\text{[15]}\)

After elution with methylene chloride and solvent phase transfer, metsulfuron methyl is determined by high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS). Using this very simple and direct approach to extraction, a minimum quantitation limit of 200 parts-per-trillion is reported.

7 PRESSURIZED FLUID EXTRACTION

7.1 History

PFE is also known as pressurized solvent extraction (PSE), ASE, pressurized accelerated solvent extraction (PASE), and enhanced solvent extraction (ESE). In its rapid adoption of several new methods employing this approach, the USEPA recognizes PFE as its official name for this technique.

7.2 Principle

PFE\(^\text{[16]}\) is carried out similarly to other techniques which utilize solvents well above their temperature and pressure at standard condition in that the solvent and the sample are placed in a closed container and heated. The heat is provided by an external oven and the solvent is pumped into and out of the extraction chamber. In this approach extractions are performed at temperatures of 373 to 453 K. In order to use common water-miscible organic solvents at these temperatures, pressures of 100 to 135 atmospheres are required to maintain the solvents in their liquid state. Under these conditions, analyte recoveries equivalent to those obtained from traditional Soxhlet extraction are achieved using much smaller solvent volumes for much shorter extraction times. Increasing temperature results in increased solubility, diffusion rate, and mass transfer, while viscosity and surface tension decrease. At elevated temperatures, the activation energy associated with desorption is more easily achieved and the kinetics of desorption and solubilization become more favorable.

The sample is enclosed in a high pressure stainless steel cylindrical cell. Following an initial heating period, it is allowed to interact statically with the pressurized solvent for a predetermined time, after which it is purged from the cell with nitrogen gas and collected in a vial. Since the extraction can be fully automated, samples can be run sequentially. Typical sample sizes for soils are in the 10–30 g range, and the total volume of solvent required for extraction and rinsing is in the 20–40 mL range. Extraction times for most pesticides are in the 20-minute range.

7.3 Applications

PFE is the most recently developed of the options analysts have for extracting pesticide residues from soils, with no published applications reports prior to 1995, and no commercial instruments available prior to 1996. Since then, however, a few applications have appeared in the research literature. Fisher et al.\(^\text{[17]}\) used PFE to extract semivolatile organic priority pollutants from a red clay loam soil, both spiked in the laboratory as well as contaminated in the field. The analyte list includes two CHIs \(p,p’\)-DDT (CAS #50-29-3) and endrin (CAS #72-20-8). Spiking levels ranged from 400 to 20 000 ppb. At spike levels between 4000 and 20 000 ppb, recoveries approached 100%. At the 400-ppb level, recoveries were lower owing primarily to matrix interference. Conte et al.\(^\text{[18]}\) report the extraction of diflufenican (CAS #83164-33-4), a pyrydylcarboxamide herbicide, from soil in 10 minutes using acetonitrile at 373 K at 30 atmospheres. Recoveries average 96% for soil spiked at 100–400 ppb. Four samples per hour are easily processed by this technique. While the high-performance liquid chromatography separation clearly shows coextracted material, presumably organic materials from the soil itself, none seemed to interfere with the retention time or shape of the herbicide peak. Pyle and Marcus\(^\text{[19]}\) extracted seven CHIs from a standard reference material (SRM) marine sediment using (1 : 1) hexane–acetone at 373 K and 135 atmospheres in 20 minutes.
The insecticides included both cis-(CAS #5103-71-9) and trans-chlordane (CAS #5103-74-2), trans-nonachlor (CAS #3734-49-4), and the p,p′-isomers of 1,1-dichloro-2,2-bis(4-chlorophenyl)ethylene (DDE) (CAS #72-55-9), 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane (DDD) (CAS #72-54-8), and DDT (CAS #50-29-3). Recoveries indicated that the combination of PFE together with quantitation by gas chromatography/tandem mass spectrometry (GC/MS/MS) is a complementary technique which is comparable to or better than existing techniques in terms of speed and sensitivity. In another report addressing chlordane extraction from soil, Brumley et al.(20) used (1:1) methylene chloride–acetone at both 373 K and 423 K for extraction completed in 20 minutes. Recoveries from soils spiked with between 2000 and 20 ppb ranged between 80 and 120% at 373 K.

PFE approaches have not been limited to insecticidal agents. The fungicide hexaconazole (CAS #79983-71-4) is effectively removed from weathered soils using acetone at 133 atmospheres and 373 K. Frost et al.(21) report that PFE furnished ‘cleaner’ extracts requiring no further pretreatment prior to chromatographic analysis than did either of two other high pressure systems. The nature of the hexaconazole–soil interaction is very important, although its ability to be recovered depends on extraction conditions and the efficiency of the system. Within the herbicide families of pesticides, triazines and chloroacetamides are two of the most widely used for weed control in corn and soybean. Gan et al.(22) have shown that PFE efficiently removes both atrazine (A) (CAS #1912-24-9) and alachlor (CAS #15972-60-8) from aged and freshly spiked soils. Following selection of a solvent system, a central composite statistical design was used to optimize extraction conditions by evaluating the effect of varying temperature, pressure, and static time on PFE efficiency. Temperature varied from 333 K to 413 K at 20 degree intervals, pressure from 33 to 166 atmospheres at 33 atmosphere intervals, and static time from 5 to 25 minutes at 5 minute intervals. A quadratic model was used to describe the interactions between each variable and the recovery. Following eight weeks of incubation the efficiency of PFE for both A and alachlor was consistently better than either Soxhlet or solvent extractions. As the herbicide on the soil ages, harsher conditions are needed to separate the residue from the matrix.

8 SUPERCRITICAL FLUID EXTRACTION

8.1 History

Experimental observations of a supercritical (SC) phase from which the property of CP for a pure substance was discovered date back to the early 1820s(23) when it was first observed that there is a critical temperature above which a pure substance can only exist as a fluid and not as either a liquid or gas. Appreciation of the solvating properties of pure substances above their CP date to 1879.(24) Early in the 1900s, it was observed that solubilities of nonvolatile organic compounds in carbon dioxide held under SC conditions were several orders of magnitude greater than that which could be explained from vapor pressure considerations alone.(25) Extraction with supercritical fluids (SFs) raised little interest during the first half of this century, and the interest shown focused on industrial process-based applications and not analytical chemistry. A new era for SFE was ushered in with a 1970 patent which described the decaffeination of green coffee beans by immersing the wetted beans in SC carbon dioxide.(26) Since 1980, there has been rapid development of applications of SFE within the food industry. At the same time applications in environmental analysis began to appear, although the initial reception by the analytical community was one of skepticism. Prior to mid-1989, fewer than 30 citations on analytical SFE could be found in Chemical Abstracts.(27) In the 1990s, the situation has reversed itself to such an extent that now more than 500 citations referencing SFE applications can be found in Chemical Abstracts for 1993 and 1994 alone.

8.2 Principle

In order to understand SFE it is helpful to review the properties of SFs. The physical state of a substance of fixed composition is described by a phase diagram, a pressure–temperature plot showing the relationship between the processes of sublimation, melting, and boiling. Shown in Figure 2 is the phase diagram for carbon dioxide. It defines the regions corresponding to the gaseous, liquid, and solid states. Points along the lines separating the phases define the equilibrium existing between the two phases. The vapor pressure of the substance begins at the triple point (TP) and ends at the CP. The critical region has its origin at the CP. Thus, an SF is any substance which is held above its critical temperature (Tc) and critical pressure (Pc). The critical temperature, therefore, is the highest temperature at which a gas can be converted into a liquid by increasing its pressure. Correspondingly, the critical pressure, therefore, is the highest pressure at which a liquid can be converted into a gas by increasing its temperature. At the CP, the densities of the two phases become identical. Thus, for pure substances held above their CP, there is only one phase and it expresses some of the physicochemical properties intermediate between those of a liquid and those of a gas. Viscosity is low and diffusivity is high, resulting in solvating power approaching polar liquids.
Using SFs for extraction of pesticides from soils offers several advantages. The solubilizing power, and thus the selectivity, can be adjusted in SFE by varying the density (changing temperature and pressure) of the SF. Often this results in cleaner extracts than liquid solvent extraction. This, in turn, reduces or eliminates the need for cleanup and facilitates quantitation by reducing analysis time while minimizing errors. By far, the most frequently used SF for pesticide extractions is carbon dioxide due to its relatively low T_C and P_C, low toxicity and reactivity, and availability in high purity at low cost. It has proven to be an excellent extractant for nonpolar pesticides, a reasonably good agent for moderately polar pesticides, and a poor extractant for polar pesticides. However, its effectiveness for the very polar analytes can be improved by the addition of polar organic solvents, known as cosolvents, as modifiers.

**8.3 Applications**

The use of SFE for extraction of many classes of pesticides from soils has received much attention in recent years. Most of this recent work has focused on current use insecticides and herbicides. Koinecke et al.\(^\text{28}\) reported that the best efficiency for SFE of the insecticides fenpropimorph (CAS #67564-91-4), pirimicarb (CAS #23103-98-2), ethyl parathion (CAS #56-38-2), triallate (CAS #2303-17-5), and fenvalerate (CAS #51630-58-1) from soil was achieved using carbon dioxide with 5% methanol cosolvent at 330 K at 375 atmospheres pressure. Complete extraction of the insecticide chlorpyrifos (CAS #2921-88-2) and its major metabolite from soil using only subcritical water was reported by Jimenez-Carmona et al.\(^\text{29}\).

Herbicides have also been a focus of SFE studies. Steinheimer et al.\(^\text{30}\) removed triazine and chloroacetamide herbicides from two Iowa soils spiked at 100–2000 ppb range using cosolvent-modified carbon dioxide. A single extraction carried out at relatively high fluid density in both static and dynamic modes sufficed for all analytes. Principal component analysis was used to correlate the response of each analyte within a matrix of dependent variables influencing extraction efficiency. Polar pesticides, including the carboxylic acid herbicides, dicamba (CAS #1918-00-9) and (2,4-dichlorophenoxy)acetic acid (2,4-D) (CAS #94-7-7), are extracted from sand using in-situ derivatization under SFE conditions, followed by direct extraction of the derivatives. However, this technique is reported to be very sensitive to matrix effects.\(^\text{31}\) Sand and a certified reference soil matrix were used to evaluate the extraction efficiency of carbon dioxide for 36 nitroaromatic compounds, 19 halogenated diphenyl ethers, and 19 insecticides.\(^\text{32}\) SFE with methanol-modified CO_2 was compared with Soxhlet extraction for twelve pesticides, six CHIs and six OPs on four soil type materials: clay, sand, topsoil, and river sediment.\(^\text{33}\) SFE was shown to have the best overall precision. The influence of both temperature and pressure on the extraction efficiencies of two N-phenylurea herbicides, diuron (CAS #330-54-1) and linuron (CAS #330-55-2), and a common metabolite from a sandy loam soil has been studied.\(^\text{34}\)

SFE has been evaluated for extraction of SU herbicides from agricultural soils. Metsulfuron methyl (CAS #7423-64-6), sulfometuron methyl (CAS #74222-97-2), and nicosulfuron (CAS #111991-09-4) were studied on three Des Moines Lobe soils from the midwestern USA spiked at 400 and 4000 ppb. The extraction procedure was optimized for metsulfuron methyl with SF density, extraction time, and cosolvent addition, as the parameters studied.\(^\text{35}\) Good recoveries (75–90%) for both metsulfuron methyl and sulfometuron methyl were obtained; however, only 1–4% of the added nicosulfuron was recovered. The authors concluded that SFE method optimization for specific compounds cannot always be extrapolated to similar compounds within the same pesticide family or to a different matrix, with respect to soil texture and composition, without additional method development and optimization.

The successes of SFs, amended or unamended, as extractants for trace organic analysis of soils and sediments has led some researchers to investigate the solvating power of liquids at elevated temperature and pressure, but well below their respective CPs.\(^\text{36,37}\) Known as subcritical fluids, they have recently been applied to some pesticide applications. Crescenzi et al.\(^\text{38}\) extracted eighteen herbicides from soil using 25 mL of subcritical water held at 363 K. The flow rate through the stainless steel cartridge containing 3 g of soil admixed with sand was increased from an initial 0.4 mL min\(^{-1}\) to 1.0 mL min\(^{-1}\). The analytes consisted of both acidic
and nonacidic herbicides; the nonacidic chemicals largely from the sym-triazine and N-phenylurea families, and the acidic chemicals largely from the chlorophenoxy acid and benzoic acid families. Recoveries from both sand and silt loam soils spiked at 100 ppb ranged between 60 and 90%. This technique of subcritical water extraction is very similar to ASE with two distinct differences; first, pressures significantly above ambient are not required, and secondly, organic solvent use is either very small or not required at all. In an extraction method comparison with 12-h methanol Soxhlet versus a 2-h sonication in a methanol–water–acetic acid mixture, the subcritical water method yielded equal or greater recoveries than both other methods for both the acidic and the nonacidic herbicide analytes.

9 MICROWAVE ASSISTED EXTRACTION

9.1 History

In the 1980s, Ganzler et al. conducted early experiments using household microwave ovens to aid in extraction conducted at atmospheric pressure. Since then, the process has been further investigated, refined, and patented. As a result, the technique has been successfully applied to extraction of organic compounds, priority pollutants, and volatile organics. That early development has resulted in specialized microwave instruments designed to provide temperature-controlled, closed-system operation. These modern units permit heating of many samples simultaneously in closed, pressurized vessels which allow for heating of polar solvents to temperatures approximately 373 K above their standard conditions boiling points. Inertness of extraction vessel surfaces in contact with the sample is assured through the use of perfluoroalkoxy (PFA) liners.

9.2 Principle

The microwave portion of the electromagnetic spectrum is defined as energy of wavelength between 3 and 300 mm corresponding to a frequency range of 1–100 GHz. Microwave assisted extraction (MAE) is the process of using this energy to heat solid sample–solvent mixtures and results in the partitioning of the compounds of interest from the solid matrix into the solvent. Typically, extraction is done in a sealed vessel under temperature-controlled conditions. This results in extraction temperatures being raised above the atmospheric conditions boiling point for the solvent selected, thereby accelerating the extraction process. The closed-vessel microwave heating systems best suited for pesticide extraction from soil usually are outfitted with a turntable to rotate the sample within the cavity, thus insuring even distribution of thermal energy.

Microwave heating is significantly different from conductive heating methods. Conductive heating is sample independent. All samples placed inside a conduction heating oven will equilibrate to the preselected temperature, a process which can be quite slow. Microwave heating is much more solute-to-solvent ratio dependent. The rate of increase in the temperature depends on the microwave-absorbing characteristics of the sample. The cavity design provides the ability to heat several samples simultaneously and uniformly in a short time with the proper oven reflectile design.

9.3 Applications

MAE of CHIs has been described by Fish and Revesz. Eleven compounds, including both cyclodiene derivatives and DDT-congeners, have been successfully recovered from certified reference soils spiked with each compound. A 1:1 acetone–hexane solvent mixture was used for extractions at selected temperatures between 363 K and 423 K with preset hold times of 15–20 minutes. Pressures ranged between 2.7 and 5.5 atmospheres. Results indicated that an extraction temperature of 293 K was the lowest at which recoveries were consistently at or above 95% for the reference soil spiked between 150 and 425 ppb for each CHI. Thermally labile CHIs, such as endrin and p,p’-DDT, showed no evidence of breakdown during the heating of the MAE process. Similarly, no loss of analyte could be attributed to the use of the PFA liners.

Successful application of MAE to pesticide removal in agricultural soils has not been limited to the hydrophobic and nonpolar end of the pesticide spectrum. A method for extraction of A together with several of its major soil metabolites has been reported by Steinheimer. In this approach, A (CAS #1912-24-9), desethylatrazine (DEA) (CAS #6190-65-4), and desisopropylatrazine (DIA) (CAS #1007-28-9) are extracted simultaneously by subjecting a soil–aqueous phase mixture to rapid microwave heating, initially in water, and subsequently with dilute hydrochloric acid. The extracts are then recovered, combined, and taken to SPE (solid-phase extraction) clean-up and prepared for instrumental determination. Recoveries from two Iowa soils, a Des Moines Lobe glacial till and a Loess Hills silt, spiked at 100–10 000 ppb ranged from 60% for A to 80%–120% for both metabolites. MAE reduced extraction times from many hours to a very few minutes while conserving costly and disposal problematic organic solvents. In another study focusing on triazine herbicides, Molins et al. report that MAE works very well for extraction of these residues from both freshly spiked soils as well as soils with spikes aged for up to 300 days. In general, the
freshly spiked soils yielded about 10% higher recovery than did the aged soils for DEA when using methylene chloride–methanol (90:10) as solvent, while A and DIA recoveries were nearly unchanged.

Among the most widely used newer classes of herbicides (post-1985 initial registration) used for both grass and broadleaf control in cash grain rowcrops are the imidazolinones and the SU compounds. Chemically, they are polar hydrophilic weak acids ($pK_a = 4$) with pH-dependent high water solubility. Extraction from soils by conventional methods is laborious and time-consuming. Stout et al.\(^{(44)}\) report that imidazolinone herbicides are extracted from agricultural soil by MAE using 0.1 M NH$_4$ OAc in NH$_4$ OH as solvent at 398 K for 3 minutes. Average recoveries of 92% with a standard deviation of 13% are reported for soils spiked at the 1–50 ppb level. MAE together with solid-phase cartridge clean-up reduces the time required to prepare a set of twelve samples for instrumental determination to <10 minutes per sample. Better extractabilities are achieved both for surface spikes and for aged field-treated soils. Liquid chromatography/mass spectrometry (LC/MS) provides a 1 ppb limit of quantitation.

MAE is reported to be very effective in addressing the issue of ‘bound pesticide residues’ and their extractability. Nicolaïer and Donzel\(^{(45)}\) have reported that MAE using 80% methanol in water at temperatures from 363 to 473 K effectively removed more of the $^{14}$C residue, both parent and metabolites, than did cold extraction in both soils and biological tissue matrices. The addition of tetramethylammonium hydroxide (TMAH) drastically improved removal from biological samples, presumably as a result of hydrolytic breakdown of polymeric matrices or cleavage of pesticide adducts, releasing residue. Herbicides studied include dimethachlor (CAS #50563-36-5), metobromuron (CAS #3060-89-7), propiconazole (CAS #60207-90-1), cyprodinil (CAS #121552-61-2), and others.

10 EXTRACTION BY SONICATION

10.1 Principle

Principles underlying ultrasonic energy form the basis for the utility of sonication to enhance solvent extraction. Ultrasound is composed of sound waves transmitted at frequencies higher than those detected and discerned by the human ear. Ultrasonic energy generated by a piezoelectric transducer oscillating at a frequency of 20,000–40,000 Hz creates cavitation in liquids. Cavitation is the formation and collapse of countless tiny cavities or vacuum bubbles within a liquid. This energy causes alternating high- and low-pressure waves within the liquid as the waves alternately expand and compress the liquid. During expansion, tiny cavities grow at a microscopic level to a maximum critical diameter and then implode with release of the energy of the sonic wave. Localized vigorous agitation occurs at the soil surface during the contraction–implosion cycles, thus releasing sorbed pesticide from the surface and into the solvent.

Many parameters affect the strength of cavitation, including frequency and amplitude of the ultrasound, temperature, surface tension, vapor pressure, viscosity, and liquid density. Direct sonication uses a specially designed acoustic tool known as the horn or probe. The entire assembly, known as the sonotrode, is constructed of an inert material, such as a titanium alloy. The sonotrode is placed directly into a soil–solvent mixture. Horns and probes are available in different cross-sectional areas and lengths depending upon the solution volume to be processed and the desired intensity. Most of the energy associated with the sonotrode occurs at its tip, and the efficiency of energy transfer to this point is critical to the performance of the probe. The agitation also generates heat, and this heat can speed sonication extractions.

10.2 Applications

USEPA Method SW-846-3350 specifies sonication as one method for the extraction of nonvolatile and semivolatile organic compounds, including pesticides, from soils. The method is based on the expected concentration of organic compounds in the sample. A high-concentration method in which the concentrations of individual organic compounds are greater than 20 parts-per-million is simple, while the low-concentration method for components with concentrations less than 20 parts-per-million uses a larger sample size, and is more complicated. The sample (2 or 30 g, depending on the expected concentration) is mixed with anhydrous granular sodium sulfate to form a free-flowing powder that can be extracted three times or more using sonication. A solvent mixture of 1:1 acetone–methylene chloride is recommended for use with a specified horn-type sonotrode equipped with a titanium tip.\(^{(46)}\) Sonication is a method of choice for extraction of polycyclic aromatic hydrocarbons (PAHs) and their hetero-atom analogs from sediments and soils but has enjoyed little adoption for pesticides. This is due to the greater popularity of alternatives, specifically, PFE and SFE, and ASE.

11 PESTICIDE BIOGEOCHEMISTRY IN SOIL: FORMATION AND EXTRACTION OF PESTICIDE-DERIVED COMPOUNDS

There are many different types of chemical reactions responsible for the conversion of pesticides to stable
daughter compounds in agricultural soils. Some are catalyzed primarily by consortia of indigenous microorganisms, including bacteria, fungi, and actinomycetes. Others are catalyzed by the surface functionality (such as dissociated silanols) found on clay mineral surfaces or the functionality of organic matter (such as carboxylic or phenolic acidity) present in the soil. In most cases, similar reactions occur for many members within a pesticide class. Within the CHI family of chemicals are both the DDT-congener and the cyclodiene adducts. For the DDT-congeners, initial degradation in the soil proceeds through either of two breakdown pathways: hydrolytic dechlorination or reductive dechlorination. In the former, chlorine is replaced with hydroxyl, and in the latter, with hydrogen. In the diverse pathway is observed for both DDD and DDE. In addition, DDT-congeners may undergo dehydrochlorination as well, as is observed in the conversion of DDT to DDE or methoxochlor (CAS #72-43-5) to methoxochlor olenin. For the cyclodiene adduct insecticides, those produced from Diels-Alder type cycloaddition of various olefins to hexachlorocyclopentadiene, initial soil breakdown usually proceeds through oxidation or dechlorination. In the case of aldrin (CAS #309-00-2) and isodrin (CAS #465-73-6), epoxidation occurs first, followed by dechlorination. In the case of dieldrin (CAS #60-57-1) and endrin (CAS #72-20-8), dechlorination occurs directly. A similar type scenario exists for the OP insecticides. All of the chemicals in this family of pesticides are derivatives of either ortho-phosphoric acid itself or one of its thiono- or thio-analogs. This circumstance is a consequence of the isoelectronic relationship between oxygen and sulfur, generally with either alkyl or aryl substitution. Initial degradation of OPs usually occurs via hydrolysis of one or more of these linkages giving rise to carbinol or phenolic acidity present in the soil. In most cases, these reactions as well as hydrolytic dechlorination reactions. Chloroacetamide herbicides undergo both hydrolytic dechlorination to carbinol derivatives and hydrolysis to their corresponding anilino-derivatives. In addition, this family of herbicides undergoes conjugation reactions with soil components which lead to both sulfonic acid and oxanilic acid conjugates. SU and imidazolone herbicides undergo hydrolysis reactions. For the SUs, cleavage of the sulfonated urea backbone produces aryl- or azaaryl-derivatives. Imidazolinones undergo a hydrolytic ring cleavage of the parent imidazolone ring with the formation of carbamoyl carbamate derivatives.

Generally, and across most families of herbicides and insecticides, soil degradation initially produces daughter compounds which are smaller (lower in molecular weight), more asymmetric in structure, and more hydrophobic (owing to the incorporation of oxygen). As a consequence, they are efficiently extracted from soils by methods which can easily accommodate polar and water-miscible organic solvents. Depending upon the ionic nature of the degradates, dilute solutions of mineral acids or bases may enhance extraction efficiency by exploiting ion-exchange properties. Research papers specifically addressing extraction of soil metabolites and degradates mostly date from 1990 and include several of the techniques previously discussed. Exhaustive methods employed for extraction of CHIs from soils also remove structurally similar degradates with equal efficiency. Both DDE, the dehydrohalogenation degrade of DDT, and DDD, the dehydrochlorination degrade of DDT, are removed from soil along with DDT by any of the five highlighted approaches. Generally, if exhaustive extraction is the primary goal, without consideration of sample throughput, time, or solvent consumption and disposal, a variant of the Soxhlet technique remains the method of choice. Generally, for the OP insecticides, the same relationship prevails: techniques suitable for extraction of the parent pesticide also remove the initial soil metabolites and degradates with approximately the same efficiency. Thus, chlorpyrifos and 3,6,5,6-tetrahydroan-2-pyridinol would be extracted simultaneously by any of the highlighted techniques.

For the major classes of herbicides, consideration of chemical properties of the target degradates makes the choice of extraction protocol somewhat more selective. In their report on SFE in which triazine herbicide
metabolites were extracted from two Iowa soils with methanol-modified CO$_2$, Steinheimer et al. demonstrated that the process variables which exerted the greatest influence on the recoveries of the two A metabolites were carbon content of the soil and water content of the methanol cosolvent amendment. In the principal component analysis, these two parameters showed highest negative correlation with recovery for both DEA and, especially, DIA. Temperature, pressure, and both static and dynamic time intervals revealed lesser correlations with recovery. DIA recoveries from loam and silt loam soils averaged about 35%, while DEA recoveries from those soils averaged about 80%.

The application of subcritical water extraction to herbicide metabolites has recently been described by Di Corcia et al. for the sym-triazine terbuthylazine (CAS #5915-41-3). This herbicide, which is not registered for agricultural use in the United States, is used as an alternative to A in Europe and elsewhere. Metabolites and degradates included all three desalkyl-metabolites: desethyl-, dest-butyl-, and desethyl,dest-butyl-. In addition, the corresponding hydroxyl derivatives of each of the derivatives were also included in the study of extraction responses. Both parent and daughter compounds are extracted together from 3 g of soil with phosphate-buffered water at 373 K. Extractant flow rate was increased from 0.3 mL min$^{-1}$ initially to 1 mL min$^{-1}$. Analytes are trapped on a graphitized carbon black cartridge and recovered by elution. The subcritical water extraction was compared to two other methods proposed for the extraction of A and its degradation products from agricultural soils: 24-h Soxhlet extraction with methanol, and the room temperature mixed-mode extractant double extraction proposed by Lerch et al. In comparison with the 24-h hot methanol extraction, the mixed-mode procedure gave the better recoveries, in spite of the fact that the soil was extracted only twice at room temperature. In contrast, the subcritical water procedure proved to be more effective in recovering the hydroxytriazine derivatives than was the mixed-mode protocol of Lerch et al.

12 AUTHOR STATEMENT

With the exception of the Soxhlet approach all of these techniques have come into prominence only in the 1990s. Accordingly, many new applications are yet to be discovered and reported. As a consequence, the author views this discussion primarily as an educational tool and not as a reference work. He has, therefore, selected only citations which illustrate principles while providing well-documented examples referencing current literature at the time of publication. Accordingly, it is the author's wish that all readers will benefit from use not only of the references cited herein, but also of the references cited within those citations listed. Many of the listed references cite research reports in which the various extraction options have been evaluated comparatively against each other for a given extraction application. These are very helpful to the reader confronted with choosing one over the others.

12.1 Disclaimer

Mention of specific products, suppliers, or vendors is for identification purposes only and does not constitute an endorsement by the US Department of Agriculture to the exclusion of others.

ACKNOWLEDGMENTS

The author wishes to thank the following individuals for their support in providing resource materials for this article: Ms Shirley Anderson, Foss North America, Edin Prairie, MN; and Dr Greg LeBlanc, CEM Corporation, Matthews, NC. The author also extends his appreciation for their review comments to the following colleagues: Dr David Meek; Dr Thomas Moorman; Dr Richard Pfeiffer; and Mr Kenwood Scoggin.

s-Triazine Herbicides and some of their transformation products (TPs) are included in both the European Communities and United States Environmental Protection Agency (USEPA) priority list of pesticides. Owing to their widespread use and toxicity profile this family of herbicides is one of the classes of chemical pollutants that are more intensively monitored by water authorities. Many analytical methods for their determination have been published. A critical overview of these methods is presented in this paper. Conventional extraction techniques are generally nonselective and can lead to analytical interferences caused by coextracted components present in the environmental matrices. Parameters affecting extraction and problems in isolating s-triazines, from water, soil, urine and food are discussed. The solid phase is particularly attractive because it may be coupled on-line with chromatographic systems. Many extraction systems, in sorbent cartridge or disk format, have been developed in the last few years.

Recently, interest has been growing in employing new highly selective materials such as molecularly imprinted polymers (MIPs) and immunosorbents to extract triazines from complex matrices. Strong cationic exchangers allow an effective clean-up and are useful to improve the sensitivity of a method. Solid-phase microextraction (SPME) is a new technique that can also be used for extracting analytes from water. This technique was successfully automated and coupled with liquid chromatography (LC). For solid matrices Soxhlet extraction is still widely used. Blending the sample in the presence of the solvent in high-speed homogenizer machines or in an ultrasonic bath ensures complete sample disruption and a better extraction of pesticides. Microwave-assisted solvent extraction, supercritical fluid extraction (SFE) and accelerated solvent extraction (ASE) are alternatives for conventional extraction procedures.

Both, gas chromatography (GC) and LC were successfully coupled with sensitive and selective detectors, but because of the legal implications, the analytical methods need sufficient specificity for testifying contamination. It has been recommended that analytical results indicating the presence of relevant concentrations should be confirmed by mass spectrometric methods. The use of chromatography with mass spectrometric detector and the most common interfaces (thermospray (TSP), electrospray (ES) and atmospheric pressure chemical ionization (APCI)) are illustrated. Rapid screening based on immunoassay and biosensor technologies are described. Finally some examples of recent applications are summarized.

1 INTRODUCTION

The herbicidal activity of s-triazine was discovered in 1952 by a Geigy Co. research group in Bern (Switzerland). The activity of this class of herbicides is based on the inhibition of the Hill reaction. The Hill reaction is one of a cascade of biochemical reactions which constitute the process of photosynthesis in chloroplasts. Some plants (corn) can degrade the Cl-triazine to an inactive compound by a reaction with a natural compound present in the plant (2,4-dihydroxy-7-methoxy-1,4-benzoxazine); some other plants (cotton) can store it in the lysiogenous gland. s-Triazines are predominantly applied in agriculture as selective pre- and post-emergence weed control of corn, wheat, barley, sorghum and sugar cane but are also widely used for nonagricultural uses (railways and roadside verges). The estimated worldwide annual consumption of atrazine in 1980 amounted to $24 \times 10^6$ kg and the annual consumption of s-triazine herbicides in USA (1992) exceeded $48 \times 10^6$ kg. Since it first entered the market in 1957, atrazine has been a very popular herbicide and in the last two decades has
become the most frequently detected pesticide in surface and groundwater.\(^5\) Because of the occurrence in the environment Italy banned atrazine in 1990 and Germany followed in 1991. In the past few years common application rates for atrazine on crops have been 2–5 kg ha\(^{-1}\) of active ingredient, in 1992 maximum application rates were reduced to 0.25–0.6 kg ha\(^{-1}\).\(^6\) Since then, maximum label-recommended application rates have been reduced further.

Triazine herbicides are rather soluble and relatively stable in water: it has been estimated that between 0.3 and 1.9% of the applied amount of atrazine on farmland has found its way into stream water.\(^7\) Their metabolites (Scheme 1) are frequently detected in groundwater. Differences in chemical structures are reflected in the physicochemical properties. \(s\)-Triazine characteristics are primarily determined by the substituent in position 2 (\(R_1\) in Scheme 1). Their basicity increases in the order \(\mathrm{Cl} < \mathrm{SCH}_3 < \mathrm{OCH}_3\) (Table 1); \(\mathrm{pK}_a\) ranges between 1.65 (simazine) and 4.46 (terbuton). The groups in positions 4 and 6 have smaller but pronounced effects on the basicity: the greater the number of alkyl groups, the more basic are the compounds.

Triazine herbicides and some of their TPs are included in both the European Communities and USEPA priority list of pesticides.\(^8\) In the USA the new Food Quality

Protection Act took water into account to determine total human exposure to pesticides.$^{9}$ In order to evaluate the risk of cancer to general population by long-term exposure, in 1994 the USEPA placed the triazine herbicides into a ‘special review’.$^{10}$

Although in 1995 DuPont announced the voluntary phaseout of cyanazine (completed in 1999), a decline of the use of this family of herbicides is not predictable.

1.1 General Analytical Considerations

In Europe the maximum allowable concentration (MAC) of pesticides and “related compounds” in drinking water is set by the European Union Commission directive 80/778/ECC.$^{11,12}$ The directive states that environmental contaminants are not acceptable in water intended for human consumption and set MAC at 0.1 µg L$^{-1}$ per substance and at 0.5 µg L$^{-1}$ for the sum of compounds. In order to determine contaminants at the 0.1 µg L$^{-1}$ level analytical methods having a limit of detection of 0.02 µg L$^{-1}$ are needed.$^{8}$

Trace analysis of polar compounds such as s-triazines in complex matrices poses serious problems:

1. When determining s-triazines and their TPs, poor recoveries from water by using either liquid–liquid extraction (LLE) or solid-phase extraction (SPE) with C18 bonded silica cartridges can be observed.$^{1,3-15}$

2. Conventional extraction techniques are generally nonselective and can lead to analytical interferences caused by coextracted components present in the environmental matrices.

3. The analytical method needs sufficient specificity for testifying contamination. Because of the legal implications it has been recommended that analytical results indicating the presence of relevant concentrations be confirmed by mass spectrometric methods.$^{8}$

4. A large-scale study will generate hundreds, if not thousands, of samples.

Accurate analysis of all the samples would be prohibitive, so a low-cost, easily accomplished screening method should be used to select the sample for analysis with the confirmation method. This approach was tested in a large-scale study on herbicides water contamination and their metabolite transport in the “Corn Belt”\(^\text{16}\). Due to their widespread use and toxicity profile this family of herbicides is one of the classes of chemical pollutants that are intensively monitored by water authorities. Many analytical methods for their determination have been published. An overview of these methods is presented in Table 2.

2 SAMPLE PREPARATION

2.1 Liquid Sample

2.1.1 Liquid–Liquid Extraction

Solvent extraction is usually carried out in a separation funnel, which is vigorously shaken to increase the contact area between the two liquids. The pH of the water sample is usually adjusted to 7 by adding phosphate buffer and, if necessary, \(\text{H}_2\text{SO}_4\) or NaOH. The extraction efficiency is improved by adding salt (usually NaCl), which has the effect of weakening water–analyte interactions. In extracting \(s\)-triazines the preferred solvents are dichloromethane, \(\text{EtOAc}\)\(^\text{17}\) and a mixture of dichloromethane and ethyl acetate and ammonium formate.\(^\text{18}\) After the extraction and phase separation, the organic phase is often dried with anhydrous Na\(_2\)SO\(_4\). The volume of the extract is reduced using a Kuderna–Danish evaporator in a water bath at 65–70 °C. Often, solvent substitution is needed to make the final extract compatible with GC analysis.\(^\text{19–24}\) The drawbacks of LLE are that it is labor-intensive, time-consuming and that it requires the use of relatively large volumes of pesticide-grade solvents, which are expensive, flammable and toxic. Even by using pesticide-grade solvents, concentration by a factor of 1000 or more can introduce analyte interferences by residual solvent impurities. Before use, NaCl and Na\(_2\)SO\(_4\) should be heated at 400–500 °C for hours to eliminate potential interferences. Vigorous shaking of solvents and water, especially surface water, may create serious problems of emulsions because of the presence of natural or synthetic surfactants in the sample. Emulsions can be eliminated only by additional time-consuming operations. Finally, \(s\)-triazine herbicide TPs are less amenable than their parent compounds to extraction with organic solvents.

Large volumes of water are better handled by a continuous liquid–liquid extractor.\(^\text{14}\) A drawback of this technique is that the extraction step takes several hours. Especially for more polar compounds – such as \(s\)-triazine metabolites – LLE is not the best choice.

2.1.2 Solid-phase Extraction

SPE is becoming the primary extraction technique for pesticides. Besides eliminating many problems associated with LLE, SPE is particularly attractive because it may be coupled on-line with chromatographic systems. Another feature of SPE is its adaptability to field extraction, by doing this organic pollutants can be isolated immediately from an aqueous matrix so that chemical and biological degradation can be avoided. Off-line SPE is commonly accomplished by forcing a water sample through the sorbent material in a small plastic cartridge by applying positive pressure or vacuum (Figure 1).

2.1.2.1 Nonspecific Sorbent

In the last few years, filter disks consisting of C18 or polystyrene-divinylbenzene (PS-DVB) sorbents imbedded in an inert material have become commercially available for SPE. Advantages claimed for disk design over cartridge one are: shorter sample processing and decreased plugging by particulate matter due to the large cross-sectional area; reduced channeling effect; and a background cleaner from interferences (Figure 2). The latter advantage derives from the fact that, unlike SPE with cartridges, the extraction apparatus with disks can consist of glass.

The performances of these two types of materials on extracting \(s\)-triazine herbicides are compared by using gas chromatography/mass spectrometry (GC/MS) detection; this method allows a limit detection between 0.06 and 0.2 µg L\(^{-1}\) in the full-scan mode.\(^\text{25}\)

It has been shown that nonselective sorbents, as derivatized silica and apolar copolymers, allow determination of many pesticides at the 0.1 µg L\(^{-1}\) level.\(^\text{26–32}\) However, the main problem is the occurrence of many coextracted and coeluting interfering compounds. Determination of pesticides at nanogram level.

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{Figure_1.png}
\caption{Schematic representation of an apparatus for off-line SPE.}
\end{figure}
levels in surface water often requires an effective clean-up step. There is a trend to develop and apply more selective sorbents. A new sorbent material is graphitized carbon black (GCB). Due to the presence of chemical heterogeneities bearing a positive charge on its surface, GCB can both be used as a reversed-phase sorbent and as an anion exchanger. \(^{33}\) \(^{34}\) \(^{35}\) \(^{36}\) N-substituted \(s\)-triazines are adsorbed on the GCB surface by nonspecific interaction, but, by exploiting the GCB double nature, separation of triazines from coextracted acidic compounds (humic acids) can be easily performed. In this way extraction, preconcentration and clean-up can be performed with a single SPE cartridge.\(^{14,35–37}\)

**2.1.2.2 Immunosorbents** Recently, interest has been growing in employing the highly selective analyte-antibody achieved by immunosorbents. In the immunosorbent, the antibody is immobilized onto a solid support and used as an affinity ligand to extract the target analytes and other compounds with similar structure from the aqueous sample. In this way, any component which is not recognized by the antibody is not retained, provided that there is no interaction with the solid support while the target analyte is bound to the antibody, leading to a high selectivity (Figure 3). Immunosorbent columns (with polyclonal and monoclonal antibodies) were used to detect \(s\)-triazines in environmental water samples by liquid chromatography/ultraviolet (LC/UV) (diode array detection, DAD)\(^{38,39}\) or liquid chromatography/mass spectrometry (LC/MS).\(^{38,40–42}\) This technique allows high recovery (except for dealkylated triazines) of many \(s\)-triazines at levels of 0.01–0.2 \(\mu\)g L\(^{-1}\) (Table 3). Baker’s yeast (Saccharomyces cerevisae) cells were immobilized on...
Table 3 Potential for class-specific immunosorbents as measured by recoveries obtained for samples spiked with a mixture of \( s \)-triazines. Recoveries measured by percolation of 50 mL of water spiked with 3 \( \mu \)g L\(^{-1} \) of each analyte. Mean values of three experiments: averaged relative standard deviation values in the range of 3–9%.

Silica gel for the selective preconcentration of \( s \)-triazines and their TPs.\(^{(39)}\)

2.1.2.3 Molecularly Imprinted Polymers Production of antibodies is laborious, time-consuming and expensive. Selective polymeric material can be prepared by the synthesis of highly cross-linked polymers in the presence of a template or “print” molecule followed by removal of the template. The remaining polymer will contain binding sites, which are complementary to the template molecule. Single or multiple interactions can describe the linking of the analyte and/or template molecules to the monomers (Figure 4). The types of interaction can be hydrogen bonds, ion pairing, \( \pi-\pi \) interaction or hydrophobic-effect-driven.\(^{(43)}\) MIPs are chemically more stable than antibodies and can cope with higher temperature and a wide range of solvents and pH. Molecularly imprinted materials have been found to exert antibody-like affinities towards the target substances and can be used for selective extraction. Highly selective MIPs can be prepared to extract triazine from complex matrices.\(^{(44–49)}\)

2.1.2.4 Supported Liquid Membrane This sample handling technique was developed by Audunsson in the mid-1980s.\(^{(50)}\) It utilizes a porous polytetrafluoroethylene membrane, which is impregnated with organic solvent immiscible in water. The organic solvent forms a barrier between the sample and the aqueous acceptor, which the analytes have to pass to be extracted (Figure 5). The supported liquid membrane (SLM) technique can be described as a two-step LLE procedure in a flow system. It is typically applied to acidic or basic compounds, but recently also extraction of permanently charged components has been demonstrated.\(^{(51)}\) A comparative study for the determination of methoxy \( s \)-triazines in natural water by SPE and SLM has shown that a considerably cleaner extract can be obtained by the latter technique (Figure 6).\(^{(52)}\) Various alkyl-\( s \)-triazines were enriched about 80 times from natural water.\(^{(53)}\) However, the SLM procedure is slow and further improvements on this technique are necessary, especially the trapping of the analyte in the acceptor solution should be enhanced.\(^{(54)}\)

2.1.2.5 Ion Exchanger Isolation of \( s \)-triazines, from water,\(^{(55)}\) soil,\(^{(56)}\) milk\(^{(57)}\) and vegetable\(^{(55)}\) extracts can be performed by using a strong cationic exchanger. Sorption of weak bases on a strong acid exchanger under strictly anhydrous conditions has been established to occur via
salt formation or hydrogen bonding. This technique allows an effective clean-up and is useful to improve the sensitivity of a method.

2.1.3 Solid-phase Microextraction

SPME is a new technique used also for extracting analytes from water. Figure 7 shows an SPME device. A 0.01–1 mm coated or uncoated fiber is immersed into a continuously stirred water sample. After equilibrium is reached (on average exposure times are 15–25 min), the fiber is introduced into the injection port of a gas chromatograph, where analytes are thermally desorbed and analyzed. Recently, SPME was successfully coupled with high-performance liquid chromatography (HPLC) and automated systems have been developed coupling SPME with GC. Parameters affecting SPME of triazine herbicides are salt effect, presence of humic acids, competition of major and minor components during the extraction process. In this experiment the polyacrylate phase was used and the sample was extracted over 30 min, followed by gas chromatography/nitrogen–phosphorus detection (GC/NPD) or GC/MS (Figure 8a and b). Six s-triazine herbicides have been identified in groundwater well samples by an 8 µm polyacrylate fiber coating and GC/NPD. The efficiency of this phase (85 µm) was also demonstrated by the time of extraction/desorption, pH and salt concentration study. A multi-residue method for the simultaneous determination of 60 pesticides (atrazine, propazine and simazine included) was developed by using commercially available 100 µm polydimethylsiloxane fibers and GC/MS.

2.1.4 On-line Solid-phase Extraction

In recent years, fully automated analysis of contaminants in water by on-line coupling of SPE to LC (Figure 9) or GC instrumentation has received increasing attention. Besides allowing rapid analysis, additional positive features of on-line SPE are that analyte loss due to evaporation does not occur and that the entire sample is introduced into the chromatographic instrument, instead of a fraction as with off-line procedures. In this way, the sampled volume can be reduced. In LC, when using a precolumn with a sorbent having a higher affinity for analytes than does the analytical column filling, broad peaks for the last eluted analytes...
Figure 8 (a) Time dependence for the equilibration of the s-triazine herbicides between the aqueous and the polyacrylate phase. (b) Effect of desorption temperature.

Figure 9 Set-up for the on-line trace enrichment of water samples where (-) represents load and (--) inject: (A, B) high pressure pumps; (C) extraction cartridge; (D) LC column; (E) detector; (F) recorder.

are obtained. In this case, backward elution of the analytes from the precolumn with the LC mobile phase can reduce peak broadening. SPE of s-triazine herbicides, using conventional reversed-phase materials (C18 or PS-DVB), immunoaffin sorbent, MIPs, was successfully coupled with GC or HPLC with UV/DAD and mass spectrometry (MS).

2.2 Solid Sample

2.2.1 Soxhlet Extraction

Soxhlet extraction is still widely used, as it allows efficient isolation of pesticides from complex solid environmental samples. Adequate analyte recoveries depend on a suitable choice of the solvent. The extraction yields also strongly depend on the nature of the matrix. Weak basic triazine herbicides can be specifically adsorbed on soil and sediment particles, thus hindering efficient extraction of residues. To obtain an efficient extraction of organics from sediment and soil samples, the solvent should be able to penetrate into the pores of the matrix. Therefore, solvents having a relatively high surface tension should not be employed. Nonpolar solvents are often not suitable for extracting pesticides trapped in the core of soils and sediments, due to a poor wettability and limited miscibility with residual water present in the samples. The wettability of a sample can be improved by just adding methanol and then the extracting solvent, for example ethyl acetate. In a more recent study, methanol was used to extract a freeze-dried soil sample for 12 h. The main drawbacks of this technique are the long time required by the extraction step and the large volume of solvent used. As an example, EPA method 3540 for extracting semivolatile organic priority pollutants, including some classes of pesticides, from soil or solid waste involves Soxhlet extraction with 300 mL of a solvent mixture for 16–24 h.

2.2.2 Batch Extraction, Ultrasonic and Microwave-assisted Extraction

Blending the sample with a suitable solvent can be effective in many cases, blending the sample in the presence of the solvent in high-speed homogenizer machines or in an ultrasonic bath ensures complete sample disruption and a better extraction of systemic pesticides.

Batch extraction of soil and corn samples with different mixtures of methanol, acetonitrile and acetone in a mechanical shaker for 90 min showed good recoveries. Chloroform, dichloromethane, diethyl ether or methanol were used to extract terbutylazine and related TPs.

Microwave-assisted extraction (MAE) is an alternative for the use of conventional extraction procedures. Water can be used to extract s-triazine herbicides and their TPs in a microwave oven while the sample is heated to 95–98 °C. This comparative study indicated that MAE with a mixture of dichloromethane–methanol (90:10, v/v) yields recoveries at least as good as those obtained by the conventional method. Moreover, the MAE procedure provides low solvent consumption in combination with a high sample throughput.

2.2.3 Supercritical Fluid Extraction

SFE has been used in industry for many years, but only recently has it been employed in the analytical field for extracting a variety of pesticides from solid
s-TRIAZINE HERBICIDES AND THEIR TRANSFORMATION PRODUCTS

Figure 10 Mixed-mode model for adsorption of hydroxyatrazine to soil. (Reproduced by permission from the American Chemical Society.)

matrices, such as soil, sediment, vegetables and animal tissues. SFE emerged as an analytical tool in the mid-1980s (Figure 10). Carbon dioxide modified with polar cosolvents, such as methanol or water, gives a high recovery of the polar analyte. Chromatograms of SFE extracts reveal fewer coextractants than seen in conventional solvent extraction. Optimal conditions for extraction are dependent on both the analyte and the soil matrix. SFE has been applied for the analysis of atrazine and its dealkylated TPs. SFE of s-triazines was also applied to freeze-dried water samples as pretreatment for GC/NPD analysis.

Figure 11 Schematic representation of an SFE device.

2.2.4 Accelerated Solvent Extraction and Subcritical Water Extraction

ASE has been proposed as an alternative for Soxhlet procedures. With this technique, a solid sample is packed into an extraction cartridge and analytes are extracted from the matrix with conventional low-boiling solvents or solvent mixtures at elevated temperature (up to 200 °C) and pressure (up to 20 MPa) to maintain the solvent in the liquid state. ASE allows extraction within a short time and with a small amount of solvent. Water has been used at ambient temperature to extract sulfonylurea herbicides and phenoxy acid herbicides from soil. Very recently, Hawthorne et al. showed the effectiveness of subcritical water in extracting chlorophenols, alkylbenzenes, polycyclic aromatic hydrocarbons and \( n \)-alkanes from a solid matrix. Class-selective extraction of these organics was achieved by adjusting the water temperature (50–300 °C). This finding was explained by the fact that the polarity of water decreases as the temperature is increased, thus making water more compatible with nonpolar organics for adsorption on soil particles or soil organic matter (Figure 11). The hot-water extraction procedure can also be called accelerated water extraction. The extraction device used to extract terbutylazine and TPs from soil by using phosphate buffer (0.5 mol L\(^{-1}\), pH 7.5) in subcritical water condition is shown in Figure 12.

Figure 12 Schematic representation of the laboratory-made subcritical water extraction device.

3 IDENTIFICATION AND QUANTITATION

The most frequently used chromatographic techniques for the analysis of the final extract are GC with
conventional and mass spectrometric detectors. Except for hydroxylated TPs, GC analysis of the s-triazine compounds can be performed without a derivatization step. In recent years, several multiresidue methods have been developed for identifying and measuring triazine herbicides by HPLC with UV or mass spectrometric detectors.

### 3.1 Gas Chromatography with Conventional Detector

Gas–liquid chromatography (GLC) on a packed column has been used extensively for the analysis of triazines with various detection methods such as flame ionization detection (FID), electron capture detection (ECD), photoionization detection (PID), Hall electrolytic conductivity detection, Coulson electrolytic conductivity detection and thermoionic (or nitrogen–phosphorus) detection.

Nitrogen–phosphorus detection (NPD) is particularly suitable for the determination of triazine herbicides (Figure 13), all of which contain five nitrogen atoms per molecule. The nitrogen–phosphorus detector is a modification of the conventional flame ionization detector in which alkali salt or alkaline-earth salt is placed in the flame (alkali flame ionization detector). This gave a response for N- and P-containing molecules comparable to that obtained with FID, but the response for other molecules was negligible. For a compound containing an N or P atom, the response may be 1000–10 000 times higher than that for the corresponding hydrocarbon. The NPD detector was also found to be about 10 times more sensitive for triazines than the electrolytic conductivity detector. To improve the sensitivity using other detectors many derivatization methods have been developed. Conversion of s-triazines into their heptafluorobutyryl (HFB) derivatives improves the sensitivity 300-fold to several thousands fold with ECD and 5- to 10-fold with electrolytic conductivity detection in the halogen mode. Trimethylsilyl derivatives of hydroxy and amino derivatives, cyanuric acid, ammelide, ammeline and melamine were separated by GLC and detected by FID. Although several USEPA methods still require the use of packed columns, GC with capillary columns, commonly referred to as high-resolution GC (HRGC) has become the standard for analyzing pesticide residues. Twenty-nine s-triazine herbicides and N-dealkylated TPs were separated on a high-resolution glass capillary coated with Carbowax 20M glass capillary column at 200 °C. In a comparative evaluation with a capillary column the sensitivity was found to be five times higher than with a packed column.

### 3.2 Gas Chromatography/Mass Spectrometry

GC/MS is a well-established technique for the trace analysis of pesticides in environmental samples. This technique has benefited from the development of fused silica capillary columns, small relatively inexpensive mass spectrometers (quadrupoles) designed to be used as dedicated GC detectors, and sophisticated computer programs to perform computerized library searches.

Compounds eluted from the GC column enter the MS ion source where ionization of molecules occurs by impact with an electron beam. As a consequence, a series of ion fragments having characteristic mass-to-charge (m/z) ratios are formed. By scanning the MS over a defined m/z range, these ions are recorded by a photomultiplier or an electron multiplier and a resulting mass spectrum is obtained which displays m/z versus relative abundance. By summing the currents produced by each fragment ion and plotting vs time a total ion current (TIC) chromatogram is obtained (Figure 14). This chromatogram does not differ from those obtained with conventional chromatographic detectors. A much more sensitive method of quantitation of a target compound is that of plotting only one or few related ion masses from the TIC chromatogram. This method is called extracted ion chromatographic profiling (EICP). By EICP, accurate and sensitive analyte quantitation can be performed in the passage of a coeluted component, provided that two conditions are met. The first one is that the coextracted component does not produce the same selected ion. The second condition to be met is that the coeluted component does not affect the ionization process of the analyte. The maximum sensitivity with MS detection can be achieved by employing the selected ion monitoring (SIM) mode.

![Figure 13 Analysis of triazine standards (1 ng each) by high-resolution gas chromatography (HRGC)/NPD: injection 250 °C, column, 30 m x 0.25 mm DB-1, 0.25 μm film; 70 °C, 0.5 min; 25 °C min⁻¹ to 195 °C, hold 8 min; 10 °C min⁻¹ to 200 °C: (A) prometone; (B) atratone; (C) propazine; (D) simetone; (E) atrazine; (F) prometryne; (G) simazine; (H) ametryne; (I) cyprazine; (J) simetryne; (K) cyanazine.](image-url)
s-TRIAZINE HERBICIDES AND THEIR TRANSFORMATION PRODUCTS

Figure 14 LC/ES/MS analysis of a spiked river water sample: (a) TIC chromatogram obtained by scanning the quadrupole filter from 40 to 220 m/z with 2-s scan time (sample spiked with 50 ng L⁻¹ of s-triazine herbicides; (b) extracted ion chromatographic profiling (EICP) (same sample) of m/z 216 (molecular ion of atrazine); (c) selected ion monitoring (SIM) of two masses (m/z 174, 216) relative to the parent ion and the fragment ion from atrazine (sample spiked with 1 ng L⁻¹). The SIM and EICP traces are similar, but the ion signal of (c) was obtained by injecting 50-fold diluted sample.

Apparently, SIM looks like EICP. The former mode differs substantially from the latter one in that one m/z value is selected before the chromatographic run with SIM, the sensitivity of the analysis can be increased by a factor of 100 or more because the MS does not waste time to collect any other ion formed. Provided that the GC is able to separate all target components from each other and provides highly reproducible retention times, simultaneous SIM analysis for a number of analytes can be obtained by a time-scheduled program within a single chromatographic run, thus fully exploiting the potential of the MS detector. The weakness of the SIM operation mode by selection of one single ion for each analyte is that false positives can occur when analyzing pesticides in complex matrices. To avoid these false positives usually the molecular ion plus one or two characteristic fragment ions are selected for each analyte. In this way, quantitation can be performed by EICP of that ion which is not generated by the interfering compound. SIM by two or three ions can lower the sensitivity of the analysis to some extent, but greatly increases the accuracy. Analysis by time-scheduled SIM is the best compromise between sensitivity and specificity of the analysis. It is particularly useful when trace analysis of pesticides down to 100 ng L⁻¹ in drinking water samples has to be performed for compliance with European standards. In this case it can be deduced that, considering that conventional GC injection devices permit introduction of 1 μL of a 500-μL final extract and that an easily interpretable background-subtracted spectrum with most MS detectors can be obtained by injecting 1–2 ng of an analyte, at least, the goal of obtaining highly diagnostic mass spectra cannot be reached by the full-scan acquisition mode. This situation however can be substantially improved by adopting large volume injector devices.

A complete study on retention behavior and fragmentation under electron-impact and chemical ionization conditions shows that: (1) the differences in retention indices of the same triazines on a column with different polarity are proportional to pKa values and to the dipole moments of these compounds; (2) under electron-impact conditions the stability of the compounds increases in the order chloro < methoxy < methylthio derivatives. Stable isotope dilution GC/MS was used for determination of low parts per billion concentrations of atrazine in water and soil. An improved method (by high-resolution MS, HRMS) with lower detection limits allows the determination of triazine herbicides in parts per quadrillion range in groundwaters.

3.3 Liquid Chromatography

Since several classes of pesticides cannot be analyzed by gas chromatographic techniques, official multi-residue methods based upon LLE/LC or SPE/LC with UV detection have been developed in recent years for a variety of pesticides including triazine herbicides and their metabolites in aqueous matrices. An additional feature of LC is that it can be easily coupled to both off- and on-line SPE. For analyzing s-triazines, the stationary phase is almost invariably silica chemically modified with reagents having an octadecyl alkyl chain. Commonly, this stationary phase is called simply C18. However, when analyzing basic pesticides, unreacted slightly acidic silanol
groups can play an important role in the fractionation process. The mobile phase is constituted by buffered water mixed with an organic solvent (usually methanol or acetonitrile). The triazine ring is a chromophore able to efficiently absorb radiations in the low UV region, that is, 210–240 nm. When operating in this region, the main drawback of the UV detector is that it can be classified as a quasi-universal detector. The main positive features of the UV detector are the high reproducibility and ruggedness, a broad linear dynamic range (10 000), a response virtually unaffected by the temperature and by composition of the mobile phase.

The most recent development in spectrophotometric detection has been the introduction of photodiode array detectors. Briefly, all the light from a deuterium lamp is passed through the sample cell onto the monochromator, which spreads out the beam into a spectrum. This falls across an array of 230–350 photodiodes mounted on a silicon chip (Figure 15). These can be read simultaneously by computer software to provide the full absorption spectrum from 200 to 700 nm every 0.1 s. In a simpler mode, the ratio of the absorption at two wavelengths can be used for analyte identification. This type of detector has a tenfold lower sensitivity in comparison to conventional UV detectors. Figure 16 shows a chromatogram obtained by analyzing 150 mL of a Seine River water sample by on-line SPE/LC/DAD. Apparently, peaks having retention times similar to those for simazine and atrazine were recorded. By comparing DAD/UV spectra, atrazine, but not simazine, was identified.

Using conventional DAD, the extremely wide range of pesticides can pose a difficult identification problem due to peak overlap. In addition, pesticides may coelute with other unknown sample constituents giving problems with quantitation. MCA, a technique that deconvolutes and quantifies known UV-absorbing substances in an unknown solution, can be used to examine the presence of a large number of pesticides from different classes in a single run. With an on-line preconcentration of 200 mL of drinking water, detection limits ranged between...
10–50 ng L⁻¹. Because the UV spectra of s-triazine are not characteristic, DAD cannot always discriminate between triazines and matrix components. Selectivity problems in the LC analysis of s-triazines in real-life matrices can be resolved only by coupling LC to a mass spectrometer.

### 3.4 Liquid Chromatography/Mass Spectrometry

Nowadays LC/MS is applied in biomedical, pharmaceutical and environmental chemistry. For polar pesticides most of the technical problems of LC/MS have been solved and for many analytes the specificity and sensitivity with this technique are similar to GC/MS. Currently, the most popular LC/MS interfaces are TSP, particle beam, APCI and ES.

#### 3.4.1 Thermospray

Besides separating solutes from the solvent mixture, the TSP interface is able to ionize compounds in solution at atmospheric pressure (Figure 17). Nonvolatile compounds can be ionized with TSP and detected with sensitivities comparable to GC/MS. Before entering the interface, the liquid flow from the LC column passes an electrically heated capillary with an internal diameter of 50–100 µm. Because of the partial evaporation in the capillary, a supersonic jet is formed that contains, in the presence of ionizing solvents, some charged droplets. Droplet charging occurs as a result of a statistical distribution of ions over the micrometer-size droplets.

While passing the heated TSP source, the size of the droplets are more and more reduced, because of solvent evaporation. As a result, ions are expelled from the highly charged surface droplets, or ions are formed by gas-phase reactions. These ions enter the MS region through a skimmer. An electrode (the repeller), with a polarity equal to that of the ions of interest and set in front of the cone, forces ions into the MS system. Ion desorption from the surface droplet is achieved by the addition of a volatile buffer salt, typically ammonium acetate, added to the LC mobile phase. In most cases, ion evaporation shows [M + H]⁺ ions for compounds with high proton affinity, such as s-triazine (Figure 18). Otherwise, [M + NH₄]⁺
ions are formed. Owing to the soft ionization process, TSP spectra often do not display fragment ions. In some cases, fragmentation can be induced by using the discharge assisted TSP technique or by using higher repeller voltages. The device increases the kinetic energy of the ions; and the collision-induced decomposition (CID) process generates fragment ions. The specificity of methods involving TSP interface can be greatly enhanced by using tandem MS. TSP has been successfully employed in the analysis of s-triazines.(26,32,112,113)

3.4.2 Electrospray

The ES interface enables the LC/MS analysis of compounds with molecular weights up to 5 000 000 Da. Eluate of the LC column enters a chamber in which a high electrical field (3.5–4.0 kV) is imposed by a power supply. This electrical field causes an enrichment of positive electrolyte ions at the meniscus at the metal capillary tip. This net charge is pulled down field, expanding the meniscus into a cone (the so-called Taylor cone). If the electrical field is sufficiently high, the cone becomes unstable and filaments are formed from which positively charged droplets (positive ionization ES mode) detach and migrate towards the counter electrode. During migration, droplets shrink because of solvent evaporation caused by moderate heating and by a counterflowing gas (drying gas). It has been postulated that, when the surface concentration of the positive charges becomes sufficiently high, repulsion forces overcome cohesive forces and droplets explode generating daughter droplets (Figure 19). This process proceeds until the droplet radius reaches the Rayleigh limit. At this point, ion evaporation competes with further reduction of the droplet size. Any analyte capable of forming adducts with protons or other inorganic cations via ion-dipole forces can form ions in the gas phase in a variety of solvents. Moreover, the ionization process appears to be nearly 100% efficient, although not all of the ions formed are sampled. A cluster of ions with solvent molecules are sampled by a cone with a small orifice (100 µm) and pass into a first vacuum chamber (ca. 1 torr), called the dissolving chamber, where a supersonic expansion occurs. There, ions are declustered by collision with the residual molecules of drying gas. The core of the expansion is sampled by two skimmers, the second one set at about 20 V, and transported to the mass analyzer region (Figure 20).

Pneumatically assisted ES uses a nebulizer gas flowing coaxially with the liquid phase to create shrink droplets. With this device, the ES source can accept more than 1 mL min⁻¹ of liquid phase (including water). Because the ES/MS arrangement is a concentration-sensitive

![Figure 19](image1.png)

**Figure 19** Schematic representation of the coulombian explosions of charged droplets in the ES source.

![Figure 20](image2.png)

**Figure 20** Schematic representation of the formation of fragment ions as a result of the collisions between [M + H]⁺ ions and residual drying gas molecules.
detectors, diverting a fraction of the LC mobile phase to another detector does not affect the sensitivity. The problems arising from the presence of relatively high amounts of salts in the LC effluent have not yet been completely solved.

In the ES process, ionization is soft, leading to the formation of [M + H]+ (positive ionization) or [M − H]− (negative ionization), even for most thermally labile and nonvolatile substances. Furthermore by increasing the electrical field in the dissolving chamber, the quasi-molecular ions can be accelerated so that multiple collisions with residual molecules from the drying gas occur generating characteristic fragment ions (Figure 21). The resulting CID spectra closely resemble those obtained by tandem MS system. In s-triazine LC/MS analysis addition of a low concentration (10−5 mol L−1) of formic acid resulted in a 60% increase of ion signal.**

3.4.3 Atmospheric Pressure Chemical Ionization

Analyte ionization can also be induced by gas phase ion-molecule reactions under atmospheric pressure conditions. Reactant ion formation is achieved by the introduction of electrons from a corona discharge located in the chamber at atmospheric pressure. The discharge, occurring at the tip of a needle held at high voltage (4–6 kV), is routinely used in combination with both pneumatic and heated nebulization. This process allows formation of ions similar to those achieved with an ES source also for less polar components. Figure 22 shows an LC/APCI/MS chromatogram and spectra of a river water sample spiked with 1 µg L−1 of atrazine. A number of papers have been published on the determination of s-triazine using LC/APCI/MS.**

3.5 Immunochemical Assay

Immunoassays are detection methods based on a reaction between a target analyte and a specific antibody. Quantitation can be performed by monitoring a color change or by measuring radioactivity, fluorescence or other physicochemical properties. The recent rapid growth in immunochemical methods is attributed in part to the availability of polyclonal and monoclonal antibodies for a variety of components of environmental significance. Another driving force in the development of immunochemical methods is the need for rapid and simple tests that can be performed on-site without requiring sample transfer to an analytical laboratory. Many immunoassay-based field-portable methods enable rapid determination of target components by personnel without an analytical chemical training.

In a typical enzyme-linked immunosorbent assay (ELISA), a solid phase (beads or the wells of microtiter plates) is coated with a hapten–protein conjugate (Figure 23). A solution of a specific antibody that has been mixed with a calibration standard or sample is then added. During an incubation period, the analyte in solution and the hapten–protein conjugate immobilized on the solid phase compete for binding to the specific antibody. Washing with buffer removes excess antibody remaining in the solution and any antibody–analyte complex that has been formed. Then an enzyme-labeled secondary antibody is added, which will bind to the antibody captured on the solid phase. Alkaline phosphatase and horseradish peroxidase are commonly used as enzyme labels. An enzyme substrate is added, causing the development of a color. Absorbance or the rate of a color development can be measured with a spectrophotometer. Quantitation is based on competition for antibody-binding sites. In this assay format, color intensity is inversely related to the concentration of analyte in the sample. A single immunoassay takes 2–24 h and many samples can be processed in parallel. Also immunoassays can be easily automatized.** The disadvantage of this method is that the enzyme can be sensitive to matrix interferences. Control samples are necessary for quantitation of matrix effects and antibody cross-reactions.

Comparative studies can be carried out, using environmental samples, between immunochemical and conventional methods such as GC or GC/MS** or HPLC.** Time-resolved fluorescence immunoassay utilizes a fluorescent label and eliminates the need for an enzyme, thus making this method potentially less susceptible to matrix interferences.** A more rapid immunoassay** utilizes a specific antibody covalently coupled to a magnetic particle solid phase that has been shown to be more precise than methods using polystyrene-coated wells and tubes.** A screening test for determination of 0.15–4.00 ng L−1 of atrazine in drinking-, well- and surface water by magnetic particle immunoassay has been approved by the Association of Official Analytical Chemists.** A dipstick immunoassay format for atrazine** and terbutylazine** determination, based on the use of polystyrol strips as antibody coating support, can be very useful as a qualitative/semiquantitative “field test” for identifying “positive” samples.

3.6 Electrochemical Biosensor

A biosensor (or immunosensor) is a device that contains a biological component (e.g. enzymes, antibodies, or cell receptors) intimately connected to a transducer (e.g. electrochemical, optical, piezoelectric, or thermistor solid-state device). Whenever an interaction occurs between the target analyte and the biological component of the biosensor, some properties of the transducer...
Figure 21 Background-subtracted CID spectra showing production of fragment ions from the \([M + H]^+\) ion for hydroxyatrazine by progressively increasing the electrical field in the desolvation chamber from (c) 20 V, to (b) 40 V, to (a) 50 V.

Figure 23 ELISA format of a field-portable immunoassay. (a) Antibody is adsorbed onto a microtiter plate or test tube. (b) The sample and a known amount of enzyme-labeled analyte are added. (c) The analyte and the enzyme-labeled analyte compete for antibody-binding sites. (d) A chromogenic substrate is added for color production. (e) The color intensity, which is inversely related to the amount of analyte in the sample, can be estimated visually or measured with a spectrophotometer. (Figure 24).

Figure 24 Schematic representation of an atrazine sensor. (Figure 24).

The substitution of membranes by MIPs of biological molecules in biosensors enables the development of a highly stable sensor that can be used in harsh environments. Stable polymeric selective membranes have been used for conductometric and fluorescence detection systems.

4 RECENT APPLICATIONS

The occurrence of pesticides and other chemicals forced authorities to organize monitoring programs in order to evaluate risks from groundwater pollution. In these
programs s-triazines play a relevant role. In 1991, the US Geological Survey started the National Water Quality Assessment program (to be completed in 2002) to assess nationwide streams and groundwater quality in 20 of the USA major watersheds.\(^5\) In this project (including analyses of 76 pesticides and 7 selected TPs) s-triazines were monitored by SPE followed by GC/MS determination. These data are the most extensive ever collected for such a wide range of pesticides and locations. A new computer tool “Geographic Information System” can easily map all these analytical data. Many other regional-scale monitoring programs were performed to assess the environmental water contamination by s-triazines. To curtail expenditure, analyses can be performed with low cost methods and confirmed by a mass spectrometric technique. This approach was used in a study on pesticides and TP transport. A rapid and inexpensive screening method such as ELISA was chosen because of its low cost per sample and GC/MS was used as the confirmatory technique.\(^16\)

Occurrence and behavior of s-triazines in closed aquatic systems such as Swiss lake basins were thoroughly studied by SPE and GC/MS\(^{131,132}\) or HPLC/UV\(^{133}\) (DAD) analysis. The impact of s-triazine herbicides on open aquatic systems, such as estuaries, were performed by analyzing water and sediments in estuarine water of the Rivers Thames, Tamar and Mersey by SPE and HRGC with nitrogen-selective detection.\(^{134}\) Another study was performed on River Ebro Delta water by LLE followed by GC/NPD and GC/MS as confirmatory technique.\(^{135}\)

Groundwater can be contaminated by the leaching of pesticides. Many researchers studied the process that governs the accumulation and transport or biodegradation\(^{137,138}\) processes of s-triazines in soil.

Personnel that handle, mix or apply atrazine to corn and other crops face potential dermal and/or inhalation exposure. To estimate this potential exposure, excretion kinetics have to be known. Residues in urine of s-triazine and its dealkylated metabolites can be determined in urine at the parts per billion level by GC/MS.\(^{139}\)

Hydrocarbons Analysis: Introduction

Peter A. Nick
Process Systems Engineering, Yorba Linda, USA

The progress of inorganic chemical analysis technology has historically been dependent upon profit motives. Medieval alchemy was driven by the need to turn base materials into treasure. During the Enlightenment, scientific chemistry work was somewhat less commercial but still typically funded by a patron intent on deriving some specific benefit. Often the true benefit(s) discovered was not what was originally intended or expected. This is a normal occurrence in science and is what keeps most of us motivated to continue to work and study in this field. Still, economic justifications are the historic motivators for most practical advances. The Industrial Age, for example, demanded the implementation of efficient ore discovery, analysis, and conversion to metal for construction and fabrication purposes. Many of the basic quantitative wet chemistry methods owe their genesis to the late 19th century when large-scale mineral mining efforts became a matter of routine and chemical analysis of the ore a part of the process.

Another significant area of fundamental chemistry also has its root in commercial opportunism. Read any organic chemistry text and one finds that the first half of the book will discuss the wide and varied chemistry of the hydrocarbon—particularly those of petroleum-derived origin.

Although originally thought of as a medicinal base, wick-lamp fuel, or coating material, crude oil and its derivatives were completely unappreciated until two somewhat independent events occurred. First, a vast array of crude oil and gas hydrocarbon reservoirs were found in the time period of the mid-1800s (Pennsylvania) through the first decade of the 20th century (east Texas and other locations). The main products distilled from this oil were fairly low-volume and low-profit retail products for consumer consumption, of the types noted above. The gas associated with the oil was sometimes burned in municipal lighting facilities but only if it did not have to be piped very far from the source. As a result, it was often flared and burned for disposal. The big nuisance product of early petroleum processing consisted of a lighter-than-water, clear liquid phase, called petroleum naphtha or “white oil”, which had a disturbing tendency to catch fire too easily and even explode violently under certain conditions. It made a wonderful solvent but was far too dangerous to be used in any significant amount by consumers and manufacturers. It usually was burned, like the gas, for disposal and was worth next to nothing, its supply far outweighing demand.

The second key development involved a technology which when commercialized would revolutionize the world and provide one of the biggest economic development engines in the history of mankind. The combustion engine, in its varied forms, was this invention, specifically the higher pressure petroleum naphtha injection-fueled version we know today. Initial engine schemes for mechanical land transport developed independently of the oil product gluts. They would utilize any type of fuel such as wood, bagasse, coal, or nearly anything else that could burn. Later versions used the heavier kerosene and gas oil streams from crude oil refining as these were reasonably abundant and relatively safe to handle. For several years overall demand for these first “mechanical horses” was limited and competition among engine types flourished.

It was when automobile makers discovered that high-compression ignition engines optimally combusted this cheap abundant material that events moved rapidly. With a growing worldwide consumer class wanting the freedom of personal transportation and two world wars demonstrating the military value of this engine technology, crude oil was soon being produced solely for its naphtha value, with the more traditional products being relegated to side-stream status. More and more research effort was put into understanding the chemistry of fuel hydrocarbons and finding ways of increasing this naphtha material production. For geographical areas deficient in petroleum, Europe and Germany in particular, derivation of naphtha-like material from much more abundant coal resources proceeded on a priority basis. The wartime fuel production efforts, especially the work to discover a means to synthesize rubber from oil, catalyzed the analysis work in all areas of hydrocarbon processing. The global economic booms in the latter half of the 20th century provided even more extreme incentives for the petroleum refining market to grow. Refinery process needs for base fuel production and requirements for increasingly stringent fuel performance specifications made analysis of these pure hydrocarbon systems a priority industrial activity. A host of derivative petrochemical and oxygenated organic chemical industries sprang up, in turn, from the roots of petroleum refining. Analytical procedures for each industry started from those used in the laboratories of the refining plants that fed them and were quickly extended into their own specific domains of need. Many of the newest analytical techniques still rely on this legacy of data to extend and validate the measurement results they produce today.

The vast portion of this technology growth occurred in the 30 years after the Second World War. During this
“golden age” of refining, a massive knowledge bank of hydrocarbon chemistry information and analytical techniques was formed, much of which has been reported in the public domain. The detail with which we know pure hydrocarbon organic chemistry is due largely to the incentives generated by this unique set of historical and economic conditions. Today, this boom-time research and development activity appears to be at work in the biopharmaceutical industries.

The industrial hydrocarbon production and processing sector is now considered a mature entity. It is in commodity-production mode with low relative margins but its products are still demanded in demand-based analytical environments. Refiners still pay most of the bills!

Based analytical environments. Refiners still pay most of the bills! A new concern – and cost generator – is that of environmental remediation. Once the public domain was thought of as a free sink in which to put wastes. As a society, we have made waste minimization and elimination just another cost of doing business – with public health issues and the attendant costs of such rightly being of considerable concern in the value-accounting process. The analytical needs of this “green” technology protocol are being driven by cost factors once again, although the current incentives are essentially negative ones (do it or else get fined!).

At the same time, analytical reporting accuracy needs went from parts per million levels at the extremes of analysis to our current parts per billion and trillion exposure levels. Many of the initial techniques regulators and industry used for environmental analytical work were developed by refiners during the “golden years” alluded to above. Improvements to these methods, particularly for wet chemistry and heavy hydrocarbon analysis, were inevitable and today a whole new discipline of environmental analytical chemistry has evolved. This encyclopedia has a major subsection devoted to the discussion of environmental and regulatory analyses of industrial wastes and the processes that produce them. Examination of these volumes by readers would provide an excellent auxiliary source of analytical techniques to complement what is presented herein. In fact, once you have absorbed what is presented in this volume, examine the remainder of the encyclopedia. Many of those techniques can be and have been successfully used in laboratory work dealing with any organic material.

While mature, the hydrocarbon production and refining sector, particularly the fuels sector, is hardly dead, despite press reports to the contrary. The unique chemical paradigm of crude oil and traditional products, i.e. hundreds of different species distributed in a wide range of molecular size, has long been a constraining factor on the type and complexity of petroleum and petroleum product analyses. Traditional analyses usually measure quantities specified in terms of some easily defined inspection parameters, boiling point and gravity being the most common.

Most newer methods of analysis that can define chemical species concentrations of the order of parts per trillion must take advantage of higher resolution analytical instruments that the computer and embedded control chip revolution has spawned. The coupling of the primary measurement hardware with powerful data and calculation servers provides a wealth of information about any material quickly. This new technology has allowed commercial hydrocarbon stocks now to be speciated and type-categorized down to the heaviest reaches of the molecular weight distribution curve. This, in turn, has opened up new vistas for the production facilities to monitor and control the processing of many potentially hazardous compounds, either to limit their production or to replace them in the process altogether. In a turn of poetic justice, high-performance liquid chromatography (HPLC) techniques originally developed for regulatory analysis of aromatics in wastewater are now used to quantify the same species in refinery conversion units such as catalytic cracking and naphtha reforming.

This symbiotic approach across industrial areas is a recurring theme in all sectors of the chemical process industries, not just the hydrocarbon sector. Knowledge begets knowledge, as one saying goes; thus we owe a debt of gratitude to those who expanded this once nascent field of knowledge into the vast array of analysis techniques available to chemists today. Just read the contents of this encyclopedia to see how much progress has been made. One cannot hope to cover the wide array of methods and techniques in use or in research today. We have tried to retain a representative sample in this volume of what currently seems to be valuable to the hydrocarbon production and refined product industry. If there is a bias towards fuel production, it is because this is still a huge economic factor in our world and will continue to be so long after the pages of the volume you read here have disintegrated into pieces. Economics still drives the development of analytical chemistry technology. Thus the reader will find the present emphasis on petroleum-based analytical environments. Refiners still pay most of the bills!
By way of categorizing the contents of this section, we include five articles on specific methodologies as applied more to product analyses of various hydrocarbon intermediate or product cuts in general.

Dr Klawun’s Hydrocarbons: Gas Chromatography Procedures for On-line and Off-line Analysis extends the discussion of gas chromatography (GC) methodology to the analysis of hydrocarbon mixtures originating from mineral oil sources as well as providing an overview of GC and detectors, including hybrid instrumentation.

The article Mass Spectrometry, Low-resolution Electron Impact, for the Rapid Analysis of Petroleum Matrices, by Drs Nero and Drinkwater, focuses on some currently nonstandard methods which can be used to determine the composition of individual components or classes of components within various petroleum matrices. GC coupled with low-resolution mass spectrometry – gas chromatography/mass spectrometry (GC/MS) – is the most useful method for quickly identifying and precisely measuring specific components or classes of components in a petroleum matrix. Direct insertion probe tandem mass spectrometry (DIP/MS/MS), used for less volatile and thermally labile petroleum components, is covered in some detail.

A “one-stop” laboratory methodology is presented by Dr S.E. Scheppele using similar but more sophisticated technology. His article entitled Mass Spectrometry, High-resolution, (Homolog)-type Analysis of Petroleum and Synfuel Distillates and Refinery Streams describes what may well be the preferred methodology of the future. Several practitioners of this type of analytical system currently exist. Most are developing their homolog databanks in confidentiality. Dr Schepele is to be commended for his willingness to discuss the University of Illinois efforts here in our compendium.

Dr Mizaikoff’s contribution on Fuel Performance Specifications, Mid-infrared Analysis of covers an old technology with a fairly new spectrophotometric frequency range – at least as applied to fuels analysis. Most spectrophotometric work with hydrocarbons today covers the near-infrared frequency range. It is often preferred for quick or even “on-line” results but usually not too accurate unless repeatedly recalibrated or used in conjunction with one or more alternative analyses such as GC or nuclear magnetic resonance (NMR) spectroscopy. The authors here present a case otherwise – at least for the mid-infrared spectrum methods.

A current “hot topic” for refinery process control is use of the near-infrared spectrophotometric range analyses. They are currently proving useful in control of octane for gasoline production and blending processes, primarily because they capture the spectral nuances of chain branching fairly well. Chain branching has a strong link to preignition tendencies (octane) in a naphtha fuel. The technology, by itself, has been successful for other analyses, too. Dr Baughman’s article Near-infrared Spectroscopy in Analysis of Crudes and Transportation Fuels will elaborate in this still-developing technology.

Finally, Nuclear Magnetic Resonance Characterization of Petroleum by Dr F.P. Miknis provides a detailed overview of this old but sophisticated technology as applied to petroleum hydrocarbons.

If the reader is curious about any analysis methodology, several articles in general are available in this encyclopedia and the instrument vendors will always be willing to supply information that may be of use.

On the theory that old is not necessarily bad, this Section Editor has composed a piece involving the utilization of the more classical petroleum analysis methods. As Dr Nero states so well in his Introduction, “Generally accepted industrials analytical procedures do not adequately define chemical composition of various petroleum products and mixtures, but these methods provide little or no information concerning specific chemical components. These industrial procedures only determine the overall physical or chemical characteristics of a petroleum product, which are necessary to market the product. Physical properties such as boiling range, density, viscosity, flash point and vapor pressures are determined. General chemical characteristics such as carbon, hydrogen, and nitrogen content, total sulfur, average molecular weight, octane number and cetane number are also determined”.

The Editor heartily agrees but these are precisely the values that commercial petroleum refiners, particularly for fuel production facilities, are most concerned about right now. They control their processes to these items and must meet certain product specifications, again involving these same quantities. The amount of quality historical data available for estimation and cross-correlation of these properties is impressive and is still being added to. Since these procedures will not die soon, we decided to discuss them for some measure of topical completeness.

Having covered some of the more important analytical techniques necessary for “adequate” characterization, our remaining articles cover the specific analytical needs of various feed and product streams themselves.

Two articles deal with the analysis of full-range crudes. Dr M.A. Ali’s contribution, Full Range Crudes, Analytical Methodology of, covers the spectrum of classical and the latest methodologies for characterizing and speciating broad boiling range hydrocarbons. The article entitled High-temperature Simulated Distillation Applications in Petroleum Characterization by D.C. Villalanti et al. describes one of the most important tools for such analyses. (O.K., if you are a purist, this article might better have been grouped with those mentioned above but...
it is an increasingly utilized technique in crude oil assay methods.)

Dr C.S. Hsu’s contribution, Diesel Fuels Analysis describes physical properties and chemical composition of diesel fuels. It addresses various issues including performance, storage stability, evaluation of refinery process efficiency and product quality, and assessment of environmental impact. Various methods of physical property measurement, performance tests, contaminant analyses, and analytical techniques for chemical composition are described.

The Editor has reprised and updated an earlier Wiley encyclopedia covering similar analytical considerations required for satisfying mandated regulatory analysis of transportation fuels. With the main emphasis of this latter article being on light naphtha (gasoline) stocks, the previous article provides a good balance for our coverage of transport fuels. It was somewhat difficult to be authoritative on actual requirements since little new legislation has been formally enacted since the mid-1990s. Many refiners are just now gearing up to meet these flats. Much is currently being discussed, however, and we try to treat these “suggestions” as what probably will be the driving legislation to come within the next few years, perhaps even by the time this volume is published.

Dr Stanley Sandler is a world-renowned thermodynamicist and his discussion of oxygenate vapor–liquid equilibrium analysis, Oxygenate Vapor–Liquid Equilibrium in Gasolines, could not be adequately covered in any other way but directly from the source himself. In his article, he reviews the equipment and measurement methods commonly used to study the vapor–liquid equilibrium of hydrocarbon–oxygenate and gasoline–oxygenate mixtures. Detailed tables indicate those oxygenate–hydrocarbon mixtures for which vapor–liquid equilibrium data are available.

Dr W.K. Robbins’ Metals, Nitrogen and Sulfur in Petroleum Residue, Analysis of considers contaminants in the residual fraction drawn off the bottom of towers or flash drums. These residues have an increased concentration of minor impurities, including sulfur-, nitrogen-, and oxygen-bearing heterocyclics, soluble nickel and vanadium compounds, and a variety of trace metals. These impurities both dominate the unique properties of the residue and play a major role in determining the refining processes necessary for its conversion to marketable products. This article introduces the common analytical techniques for the measurement of sulfur, nitrogen, nickel, vanadium, and trace metals in this challenging organic matrix.

Dr Bacaud’s Petroleum Residues, Characterization of deals with the analytical classification of speciation types and prediction of properties of residue streams in general. Distinctions are drawn between atmospheric and vacuum residues. Since the simplest, lighter constituents of petroleum have been separated by distillation, residues concentrate the most complex fraction of crude oil and a detailed inventory of the individual compounds is impossible. Thus characterization methods will aim at giving an adequate description of the types of compounds contained therein.

A lubricant is a substance that reduces friction and wear between surfaces. Base oils typically comprise 80–99% of the finished lubricant. They are refined from selected crude oils, re-refined from used oil, synthesized from specific organic compounds, or extracted from renewable resources, such as seed oils. Base oils formulated into finished lubricants help to reduce friction and wear between moving surfaces, remove heat, seal, cushion against shock loads, and remove abrasives and contaminants from the lubricated area. Because of the special handling and processing required for lubricant stocks, we have three articles dealing with their analysis and characterization.

Dr Shugarman’s article, Lubricant Base Oils: Analysis and Characterization of, is concerned with the lubricant base oils, or base stock. These stocks are combined with performance additives to make finished industrial and automotive lubricants. Base oil analysis and characterization is important for understanding how the physical and chemical properties of these materials relate to performance in finished lubricants. It is also essential for maintaining quality control over the manufacturing process, quality assurance of the finished product, and for setting specifications between buyer and seller.

Lube Products. Molecular Characterization of Base Oils, by Dr Montanari, covers the other end of lube technology. Finished oil considerations include final product specifications which are nearly as varied as those of transport fuel. The author shares some of his career’s work in this area.

Dr J.G. Groetsch has written Refractive Index Technology as a Real Time Viscosity Technique, which describes the use of an online digital process refractometer to determine the viscosity index of lube oil stocks. Since lube oils are Newtonian fluids, refractive index can be related to viscosity index. Real-time continuous measurement of the lube stock refractive index has eliminated sampling; improved product consistency, reduced waste, and helped to optimize the process.

Oil shale is an alternative source of liquid hydrocarbons. The organic matter in an oil shale is mostly in the form of kerogen, which is defined as that fraction of the organic matter in a sedimentary rock that is insoluble in common petroleum solvents. The insolvability of kerogen is the main reason why an oil shale must be heated to produce liquid products. As with petroleum, standard assays do not provide information...
about what chemical properties of oil shales are important for producing liquids. Consequently, a number of alternative procedures have been developed to analyze oil shales. These procedures, along with methods of analyzing shale oils, are described in the article *Oil Shale and Shale Oil Analysis*. The Editor feels that most of these techniques would be appropriate, along with aromatics analysis techniques presented elsewhere in this volume, for the characterization of coal-derived liquid hydrocarbons.

With that, we have covered pretty much the whole range of hydrocarbons. Some of these methods work well for any multicomponent organic liquid but this is something for you the reader to decide. We hope we have been able to present the current state of hydrocarbon analysis in its many flavors.

Diesel Fuels Analysis

Chang S. Hsu
Exxon Research & Engineering Co., Annandale, NJ, USA

1 Introduction

Diesel fuels are analyzed for their physical properties and chemical composition to address various issues including their performance, storage stability, evaluation of refinery process efficiency and product quality, and assessment of environmental impact. Various methods of physical property measurement, performance tests, contaminant analyses, and analytical techniques for chemical composition are described.

1 INTRODUCTION

Diesel fuels are the fuels used in diesel or compression ignition engines. In diesel engines, the air is compressed to high temperature before the fuel is injected into the cylinder to ignite or detonate. Compared to spark ignition engines, a diesel engine is cost effective because of its operating advantages, greater efficiency, high power output, and fuel economy under all loads. However, it has disadvantages of noise and emissions of particulates and nitrogen oxides (NOx). Three grades of diesel fuels are in common use: (1) land diesel fuels, used in trucks, buses, trains, or other land transportation vehicles that have high variation of speed and load; (2) marine diesel fuels, used in ships that have variable speed but relatively high and uniform load; and (3) plant diesel fuels, used in electric power generation plants that have low or medium speed with heavy load. Hence, the quality of the diesel fuels depends on the performance requirements of the engines.

Today, the majority of diesel fuels are derived from petroleum, although some may come from other fossil fuel resources such as coal liquefaction fractions and through synthesis, such as Fischer–Tropsch distillates. The quality of diesel fuels can vary significantly owing to differences in the crude oils from which the fuels are derived and the refinery process streams from which they are blended. For example, there are significant differences in composition between straight run and hydrotreated cracked diesel streams. Diesel fuels taken from refinery streams for land transportation are the lightest and narrowest distillation cuts, while those for power plants are the heaviest and broadest cuts (fuel oils). The plant diesel fuels also contain the highest concentrations of sulfur and other heteroatoms.

The main sources of diesel fuels from refinery streams are straight run middle distillates from atmospheric and vacuum pipestills (distillation towers). Other streams that may be blended into the diesel pool include heavy cracker naphtha/oils and light coker oils. These streams are often hydrotreated to improve stability and to reduce sulfur and aromatics content. The most important properties of refinery streams for diesel blending include cetane number, initial boiling point (IBP), 95% boiling point, American Petroleum Institute (API) gravity (density), and viscosity. Cetane number is governed by industrial specifications. Among refinery streams that are blended into diesel pools, virgin middle
distillates and hydrocracker bottoms have the highest cetane number (35–60). Light catalytic cracker oil (LCCO) has the lowest cetane number (<20) and is generally blended with high cetane number streams to reach a cetane number >40 for land and marine (transportation) diesel fuels and >30 for plant (industrial) diesel fuels.

Diesel fuels are analyzed for their physical properties and chemical composition to address various issues including their performance (combustion efficiency), storage stability, evaluation of refining process efficiency and product quality, and assessment of environmental impact.

2 METHODS FOR PHYSICAL PROPERTIES MEASUREMENT

Physical properties of diesel fuels are measured to determine the ease of volatilization and flow in fuel lines and the storage stability of the fuels. The properties to be measured generally include boiling point, flash point, cloud point, pour point, density, viscosity, and color.

There are many established methods for measuring physical properties of diesel fuels. The American Society for Testing and Materials (ASTM) and the Institute of Petroleum (IP) have published standard methods for such measurements.\(^1\,2\) Some of the important tests that are generally included in fuel specifications are briefly discussed below.

2.1 Boiling Range

Boiling range (or distillation limits) is measured to ensure that fuel products have suitable volatility. The boiling range is defined as the temperatures between the IBP and the final boiling point (FBP). The temperature at which 95% of the fuel has evaporated (T95) is frequently specified. The boiling range of diesel fuels can be obtained by the low efficiency ASTM D 86 (IP 123) test method or by ASTM D 2892, which gives true boiling point measurements using a 15-theoretical plate column. However, both ASTM D 86 and D 2892 require a rather large volume of sample. Boiling range distributions (distillation curves) of diesel fuels have therefore been more conveniently determined using gas chromatography (GC), ASTM D 2887. This so-called “GC simulated distillation” method uses a GC column coated with nonpolar methyl silicone as a stationary phase. After calibration, the retention times of the components are essentially equivalent to the true boiling points determined by ASTM D 2892. The boiling range for typical land transportation diesel fuels is between 350 °F (177 °C) and 650 °F (343 °C), although for some diesel fuels the IBP and/or FBP are slightly out of this range.

2.2 Flash Point

Flash point is used to determine the temperature at which the vapor space above the fuel can be ignited by a spark or other ignition source. The flash point of a diesel fuel can be determined by ASTM D 93 (IP 34) using a Pensky–Martens closed cup tester or by ASTM D 56 using a Tag closed tester. In the test, the sample is placed in a cup of the tester with the lid closed. The lowest temperature at which a small flame of a specified size causes the vapor above the sample to ignite is recorded as the flash point. Flash points of transportation diesel fuels are generally >40 °C. Fuel oils used for low- and medium-speed engines have a minimum flash point of 55 °C.

2.3 Low-temperature Flow Characteristics

Either ASTM D 2500 (IP 219) or D 3117 test can be used to determine the temperature at which a cloud of wax crystals first appears in fuel when it is cooled. The temperature is recorded as cloud point. The cloud point of a diesel fuel is typically +10 to −40 °C.

The lowest temperature at which a fuel stays fluid is recorded as its pour point, as determined by ASTM D 97 (IP 15). A typical diesel fuel has a pour point between −10 and −40 °C.

There are a number of filterability tests. In some cases they supplement the measurements of pour point and cloud point, and are particularly useful for evaluating fuels containing flow improver additives. In the ASTM D 4559 test, the temperature of the test fuel is lowered at a controlled cooling rate. The lowest temperature at which a fixed volume of the fuel can be filtered through a specific mesh (17 µm) of screen in less than a given period of time (60 s) is recorded as minimum low-temperature flow test (LTFT) pass temperature. In Europe, the standard test method for cold-flow performance of diesel fuels is the cold filter plugging point (CFPP), designated as EN116 (identical with IP 309).\(^2\,3\) CFPP is the highest temperature at which a given volume of fuel fails to pass through a standardized wire mesh filter under a controlled vacuum in a specified time, when cooled under standardized conditions.

Cloud point, LTFT, and CFPP are measured for vehicle operability. Pour point is for fuel distribution system in the vehicle.

2.4 Density/Relative Density (or American Petroleum Institute Gravity)

There are two standard methods adopted by ASTM for density measurement. The D 1298 (IP 160) method uses
a hydrometer that is immersed in a test fuel at a specific temperature, and the D 4052 (IP 365) method uses a digital analyzer consisting of a U-shaped, oscillating sample tube and a system for electronic excitation, frequency counting, and display. The relative density (specific gravity) at 60 °F can also be represented by API gravity.

\[
\text{API gravity, deg} = \frac{141.5}{\text{specific gravity at 60}^\circ\text{F}} - 131.5
\]

Typical densities of transportation diesel fuels at 15 °C (60 °F) are 0.80–0.86 g mL⁻¹, or 33–45 °API gravity.

### 2.5 Viscosity

The kinematic viscosity of diesel fuels is important to their effective use, e.g. for flow of fuels through fuel lines, injection nozzles, and orifices. In the ASTM D 445 (IP 71) test, a fixed volume of fuel flows through a calibrated viscometer under a reproducible driving head and at a closely controlled temperature. The kinematic viscosity is the product of measured flow time and the calibration constant of the viscometer. Dynamic viscosity is obtained by multiplying the measured kinematic viscosity by the density of the fuel. The kinematic viscosity range of transportation diesel fuels at 40 °C is 1.3–4.1 centistokes (cSt or mm² s⁻¹) with most being between 1.9 and 4.1 cSt. The kinematic viscosity of fuels used in heavy-duty low-speed engines is in the range 5.5–24 cSt.

### 2.6 Aniline Point

Aniline point is not generally used any more for estimating the aromatics content of a fuel. To determine the aniline point, a specific volume of aniline is mixed with the fuel, as in the ASTM D 611 (IP 2) test method. The mixture is cooled at a controlled rate. The temperature at which two phases separate is recorded as the aniline point. Aniline points are high for paraffins and low for aromatics with cycloparaffins and olefins in between. The aniline point has been found to be highly correlated with the cetane number of diesel fuels.

### 2.7 Color

Color is used as an indication of fuel quality. A variation outside the established range may indicate degradation or contamination of the fuel with other products. It is not, however, a reliable predictor of stability. A scale ranging from 0.5 to 8.0 is used in the ASTM D 1500 (or IP 196) test, which employs a standard light source and a comparison of colored glass disks.

### 3 PERFORMANCE TESTS

One of the most important tests for diesel fuel performance is cetane number, a measurement of the ignition quality of fuels in a diesel engine. For usage and storage, standard tests for heating value, lubricity, filterability, corrosivity, and oxidation stability of the fuel have also been established.

#### 3.1 Cetane Number

The cetane number of a fuel is measured on a single-cylinder rating engine by comparing the fuel performance with blends of \(n\)-hexadecane and \(\alpha\)-methylnaphthalene or heptamethylnonane. A diesel fuel with cetane number 55, for example, matches the performance of a blend of 55% of \(n\)-hexadecane and 45% of \(\alpha\)-methylnaphthalene in the cetane engine.

Methylene groups (CH₂) not incorporated in naphthenic rings and more than three carbon atoms from any other structures (such as aromatic rings, methyl groups, double bonds, or naphthenic rings) are the single most important molecular features for cetane number. The molecules with highest cetane number are the straight-chain normal paraffins. The molecules with lowest cetane number are those having few methylene groups. The presence of double bonds in molecules will lower the cetane number. Hence, the general trend of cetane number among the molecular types is \(n\)-paraffins > isoparaffins > cycloparaffins > aromatics. Within a homologous series, for example the paraffins, the cetane number increases with molecular weight.

Typical cetane number ranges of refinery process streams are: virgin distillate streams—light (jet), 35–46, mid (diesel), 35–60, heavy (light virgin gas oil), 46–56; LCCO, 14; heavy coker naphtha (HKN), 37; light coke gas oil (LKGO), 40–45; and hydrocracker fractionator bottoms, 42–58. These streams may be blended into diesel fuel pools.

#### 3.2 Cetane Index

Various correlations between cetane number and other measured properties are in use. Frequently these correlations are proprietary or limited to restricted groups of diesel fuels. For the determination of cetane number, an engine performance test uses a large volume of fuel over a rather long period of time. In addition, the engine requires extensive and continuous maintenance to assure the quality of cetane ratings. Hence, ASTM has developed two cetane indices that refineries generally use for estimating the cetane number of diesel fuels. In ASTM D 976 (IP 264), the cetane index is calculated from API gravity and ASTM D 86 mid boiling point (T50). An
alternative method for estimating cetane number of a transportation diesel fuel is the ASTM D 4737 (IP 380), a four-variable method that uses density and 10% (T10), 50% (T50), and 90% (T90) recovery temperatures of the fuel as variables.

Cetane index does not reflect the use of cetane improver, but correlates with the aromatics of the fuel.

3.3 Heating Value
The heating value or energy content of diesel fuel affects fuel economy and power output. Standard methods for heating value measurement include ASTM D 4809 for transportation diesel fuels and ASTM D 4868 for plant diesel fuels. Typical heating value for land diesel fuels is 134 000 Btu gal⁻¹ (or 19 700 Btu lb⁻¹); for marine diesel fuels, 138 000 Btu gal⁻¹; and for plant diesel fuels, 148 000 Btu gal⁻¹.

3.4 Lubricity
Lubricity of diesel fuel can affect the life of engine components such as fuel injection pumps. There are many methods for evaluating diesel lubricity. ASTM has standardized two methods: high-frequency reciprocating rig (HFRR) as ASTM D 6079 and scuffing load ball on cylinder lubricity evaluator (SBOCLE) as ASTM D 6078. The HFRR method has also been standardized by ISO (International Organization for Standardization) as CEC F-06-A-96. No absolute correlation has been developed between these two methods or between these methods and field performance.

In the ASTM D 6079 (HFRR) test, a fixed volume of the fuel is placed in the test reservoir. During the test, a vibrator holding a nonrotating steel ball loaded with a specified mass (e.g. 200 g) is lowered to contact a disk that is completely submerged in the fuel. At a specific test temperature, the ball rubs against the disk with a 1-mm stroke at a frequency of 50 Hz for 75 min. The wear scars on the ball are measured under a microscope with a 100 × magnification. Typical results are 250 (good) and 600 (bad) μm. The target is currently set at <460 μm.

In the ASTM D 6078 SBOCLE test, a load arm holding a nonrotating chrome alloy steel ball is lowered to contact a partially fuel-immersed polished steel test ring rotating at a specific speed (e.g. 525 rpm). The ball rubs against the test ring for a given period of time, and the tangential friction force is recorded. Tests can be performed with a single load or incremental load following prescribed procedures. Typical incremental load results are 2500 to 5000 g, with >3100 g considered as good lubricity.

3.5 Corrosivity
The corrosivity of diesel fuels can be measured by the ASTM D 130, jointly with IP 154, copper strip tarnish test. A polished copper strip is immersed in a given quantity of fuel sample and heated at a specific temperature for a given amount of time. The copper strip used in the test is then compared with an ASTM Copper Strip Corrosion Standard to classify the corrosivity of the fuel.

3.6 Stability
The stability and the quantity of insoluble material formed during storage of diesel fuels under air over a given period of time can be tested by ASTM D 4625 (or IP 378). In this test, fixed volumes (400 mL) of filtered fuel are aged in borosilicate glass containers at 43°C for periods of 0, 4, 8, 12, 18, and 24 weeks. After aging for a selected time period, the total amount of filterable and adhesive insolubles is measured after a sample is removed from storage and cooled to room temperature. This method is not suitable for quality control testing because of long storage periods, but it can be used as a tool for studies of fuel storage properties.

There are two accelerated oxidation tests adopted by ASTM. In the method of D 2274, a fixed volume of fuel is bubbled with oxygen at a specific rate and temperature for a given period of time. The total amounts of filterable and adhesive insolubles formed during the test are measured as mg per 100 mL. The second acceleration test, ASTM D 5304, uses an oxygen overpressure. In this test, 100 mL of fuel, with or without stabilizer additives, is placed in a borosilicate container that is then placed in a pressure vessel preheated at 90°C. The vessel is then pressurized with oxygen to 100 psig (pounds per square inch) (800 kPa) and placed in a forced air oven at 90°C for 16 h. The sample is cooled at the end of test to determine gravimetrically the amount of fuel insolubles. This method achieves acceleration of oxidation without resorting to higher temperatures.

A thermal stability test method of diesel fuels is under development in ASTM, which is based on Octel/Dupont F21-61 Accelerated Fuel Oil Stability test. In this test, 50 mL of fuel is passed through a 200-mesh filter at 150°C for 90 or 180 min. The reflectivity of the filter under a standardized light is measured to determine the thermal stability of the fuel.

4 ANALYSES OF FUEL CONTAMINANTS
Water and ash contents are contaminants in diesel fuels. They are measured to meet specifications that are agreed upon between purchasers and suppliers at the time and place of delivery.
4.1 Water and Sediment

Water and sediment in diesel fuel can cause increased corrosion, filter plugging, and engine damage. In ASTM D 1796 (IP 75), a mixture of equal volumes of fuel and water-saturated toluene is centrifuged, after which the volumes of the water and sediment layers are read.

4.2 Ash Content

The amount of ash-forming material in diesel fuel is measured to determine whether the fuel might have unacceptable deposits on combustion. Ash can come from oil- or water-soluble metallic compounds or from extraneous solids such as dirt and rust. In the standard ASTM D 482 (IP 4) test, a weighed sample is burned in a vessel until ash and carbon remain. The carbonaceous residue is then placed in a muffle furnace at 775 °C to reduce it to a carbon-free ash; it is weighed after it has cooled to room temperature.

4.3 Carbon Residue

The carbon residue of base fuel without additives can indicate the coke-forming propensity of the fuel when used in pot-type and sleeve-type burners. In the standard ASTM D 524 (IP 14) test, a weighed sample is placed in a glass bulb with a capillary opening; the bulb is heated in a metal D 524 (IP 14) test, a weighed sample is placed in a glass bulb with a capillary opening; the bulb is heated in a metal furnace at 550 °C and water-saturated toluene is centrifuged, after which the volumes of the water and sediment layers are read.

5 ANALYTICAL TECHNIQUES FOR CHEMICAL COMPOSITION

Diesel fuels are mainly composed of hydrocarbons, with minor or trace amounts of sulfur-, nitrogen-, and oxygen-containing compounds. The determination of chemical composition of diesel fuels involves both standard tests and nonstandard instrumental analysis.

5.1 Elemental Analysis

In addition to carbon and hydrogen, diesel fuels contain trace amounts of sulfur, nitrogen, oxygen, and other elements. The hydrogen-to-carbon ratio can be used to assess fuel characteristics and refining process performance. Sulfur and nitrogen contents are environmental concerns. Like the hydrogen-to-carbon ratio, they can also be used to assess the efficiency of upgrading processes at refineries. Carbon, hydrogen, and nitrogen contents (CHN analysis) can be simultaneously determined using instruments, as described in ASTM D 5291. In this method, the sample is combusted at 950–1020 °C. The combustion product is passed through calcium oxide to remove sulfur oxides. The remaining combustion gas is then passed over a heated copper train to remove excess oxygen and reduce nitrogen oxides (NOx) to N2. The final gas mixture of N2, CO2, and H2O is separated by a heated gas chromatographic column and measured by a thermal conductivity detector. Alternatively, the gas mixture is passed over NaOH to remove CO2 and then over magnesium perchlorate to remove H2O. A thermal conductivity cell measures the remaining N2. Simultaneously, but separately from the nitrogen measurement, the carbon and hydrogen are determined by measuring the CO2 and H2O levels using infrared (IR) cells.

There are several standard methods for the sulfur measurement. In a combustion method for samples with 0.1% sulfur (ASTM D 129), the sample is combusted in a closed bomb containing oxygen. The sulfur content is determined by weighing barium sulfate in the bomb washings after reaction with a known amount of barium chloride solution. Another method adopted by ASTM, D 1552, is to combust the samples that contain at least 0.06% sulfur in a stream of oxygen. The combustion product is continuously absorbed in an acidic solution of potassium iodide with starch indicator. Potassium iodate is added to the absorber solution to maintain the solution as a slightly blue color. The amount of potassium iodate consumed during combustion is used to determine the sulfur content.

The sulfur content can also be determined by instrumental methods. For samples containing 0.05 to 0.5 mass% sulfur, ASTM D 4294, using energy dispersive X-ray fluorescence (EDXRF) spectroscopy, can be employed. For samples with less sulfur, ASTM D 2622, a method that is based on the measurement of the Kα line at 5.373 Å (1 Å = 10−10 m) by wavelength-dispersive X-ray spectrometry after background subtraction, can be used. However, care should be taken to avoid or to correct for interference from other elements as impurities in the sample.

The oxygen content of the fuel is usually of little concern. It can be obtained by taking the balance of the CHNS analysis, i.e. 100% minus the percentages of the four elements. More accurate measurement can be obtained by neutron activation analysis (NAA), in which the sample is bombarded by high-energy (~14 MeV) neutrons. The intensity of the γ-rays emitted from the nuclei at a known time after the sample has been neutron irradiated is measured to determine the concentration of the element.

5.2 Chromatography

Diesel fuels can be separated by chromatography according to polarity and boiling point. Polarity separation is...
normally carried out in liquid phase by liquid chromatography (LC), while boiling point separation is carried out in gas phase by GC. In general, liquid-phase separation has low resolving power that can separate components only into compound type groupings. High resolving power to resolve individual components is achievable with gas-phase separation. However, because of the large numbers of components present in diesel fuels, co-elution of components is common even with high-resolution GC using capillary columns.

5.2.1 Liquid Chromatography

Several standard liquid chromatographic methods have been established for diesel analysis. A simple test for determining the concentrations of aromatics and olefins in diesel fuels uses a fluorescent indicator adsorption (FIA) method, ASTM D 1319. The sample is introduced into a glass adsorption column packed with activated silica gel, with a small layer of the gel containing a mixture of fluorescent dyes. After all the sample is adsorbed onto the gel, alcohol is added to desorb the sample down the column. Aromatic, olefinic, and saturated hydrocarbons are separated according to their affinity with the gel. The dyes are also separated with hydrocarbon types. The boundaries of different hydrocarbon zones can be made visible under ultraviolet light. The volume percentages of aromatics, olefins, and saturates are calculated from the length of the zones.

A standard high-performance liquid chromatography (HPLC) method, IP 391, has been adopted by the European Community. It utilizes a polar column and refractive index detection to measure the amounts of saturates (nonaromatic hydrocarbons) and mono-, di-, and polynuclear aromatic hydrocarbons. In this method, a known mass of the sample is diluted in a nonpolar solvent, such as heptane, and a fixed volume of the solution is injected into a HPLC setup with a polar column (normal phase HPLC) to separate components according to aromatic ring types. Nonaromatic hydrocarbons that have little affinity with the column elute first, followed by mono- and diaromatic hydrocarbons. Then, the column is backflushed to elute the polynuclear aromatic hydrocarbons as a single peak. The column temperature is maintained constant (±1 °C) within the range 20–40 °C. However, the responses of the refractive index detector to hydrocarbon molecules depend on the structure, and they vary greatly with different types of molecules. Hence, careful calibration in response factors is necessary to ensure accuracy of the quantitative measurement. Photodiode array (PDA) detection can be used for distinguishing and identifying the aromatic type of the components. However, its use for quantitation is also limited by nonuniform responses for various types of aromatic hydrocarbons.

5.2.2 Supercritical Fluid Chromatography

Supercritical fluid chromatography (SFC) with flame ionization detection (FID) has proven to be quite effective for the determination of the total amount of aromatics in diesel fuels. It has become a standard ASTM method (ASTM D 5196) for the determination of aromatic content and polynuclear aromatic content of diesel fuel. A small volume of the sample is injected onto a packed silica column and eluted using supercritical carbon dioxide as the mobile phase. Monoaromatic and polynuclear aromatic hydrocarbons are separated from nonaromatic hydrocarbons (saturates and mono-olefins, if present). The resolution among different aromatic types is poor, especially for the distinction between di- and triaromatics. However, the relatively uniform response of FID for different hydrocarbon types is an advantage of this method.

A more elaborate SFC separation scheme has been suggested by Andersson et al. It uses multiple columns and supercritical carbon dioxide as a mobile phase to determine saturated compounds (paraffins and naphthenes), olefins, mono-, di-, and triaromatics, and polar compounds in diesel fuel distillates. Using a valve switching technique, compounds are retained and then eluted from the multiple columns at different times. During the compound retention period, polar compounds are retained in a cyano-bonded column, aromatics in a silica column, and paraffins and olefins in a silver-impregnated column. During the elution period, aromatics are eluted from the silica column first, after which the polars are back-flushed from the cyano-bonded column. Saturates are then eluted from the silver-impregnated column, followed by back-flushing the olefins from the silver-impregnated column. A mass spectrometer coupled with SFC is used to provide the basis of column switching, to select integration limits, and to obtain more detailed distributions of compound types.

5.2.3 Gas Chromatography

GC has been used for routine analysis of volatile complex organic mixtures. Although many different stationary phases can be used, the most common columns in GC analysis are coated with nonpolar methyl silicone. With a nonpolar GC column, components are separated essentially by boiling point. This correlation between boiling point and GC retention time is the basis for using GC simulated distillation, described earlier, to estimate yields of petroleum distillates, including diesel fuel streams. For general quantification, FID is used because of its uniform response across various hydrocarbon types.

GC with element-specific detectors can conveniently measure small or trace amounts of sulfur- and nitrogen-containing components in diesel fuels. Specific detection is important not only in quantifying trace amounts of
heteroatom-containing compounds without interference from the overwhelming hydrocarbon components, but also in helping combined gas chromatography/mass spectrometry (GC/MS) to focus on retention time regions in identifying heterocompounds of interest.

Atomic emission detectors (AED) can simultaneously detect several elements including C, H, N, S, and O. The GC effluent is introduced into a capillary tube containing Pt/Rh catalysts at 850–1300 °C to form carbon monoxide, which is then converted into methane as it flows through a hydrogenator following the cracker. A flame ionization detector detects the resulting methane.

Mass spectrometry alone has also been used for hydrocarbon type analysis of diesel fuels and other middle distillates. The concept of hydrocarbon type analysis is to use mass spectral fragment peak summations, respectively characteristic of compound types to be determined. Numerous components are grouped into a few compound types as paraffins, cycloparaffins, monoaromatics, diaromatics, polynuclear aromatics (3+-ring aromatics), and sulfur compounds. Sulfur compounds (benzothiophenes, dibenzothiophenes, and benzanthothiophenes) are the only heterocompound-containing compound types included in the analysis. These are the major compound types typically found in diesel fuels. Due to overlaps of mass series of certain saturated and aromatic hydrocarbons, the sample is preferably separated by elution chromatography, e.g. modified ASTM D 2549, into saturates and aromatic fractions before the mass spectrometric analysis. The separated fractions are analyzed by mass spectrometry using ASTM D 2425 for both or ASTM D 2786 for saturates and ASTM D 3239 for aromatics.

The most detailed compositional analysis of diesel fuels can be obtained by GC/MS, in which a gas chromatograph separates components before their elution into a mass spectrometer for characterization. However, because of the numerous components in diesel fuels, complete or near-complete separation of individual components by GC is impossible. Hence, for trace components, open column, HPLC or other types of chemical separations are often used to concentrate components of interest (typically heteroatom-containing compounds) for GC/MS analysis with minimal interference from the predominant components.

Further analysis, relatively pure fractions can be obtained by chromatographic procedures that fractionate the sample into saturates, monoaromatics, diaromatics, polyaromatics, and nitrogen/oxygen compounds (polars). Each fraction can then be characterized by GC/MS for the identification of isomers. Many of these fractions can be further separated by thermal diffusion for greater enrichment of various subtypes, i.e. paraffins, alkylbenzenes, naphthalenes, etc. The carcinogenic, teratogenic, and/or mutagenic activities of polycyclic aromatic hydrocarbons (PAHs) are isomer specific. Diesel fuel can be separated by solid phase extraction into saturates, mono-, di-, and polyaromatic hydrocarbons. The 2- and 3-ring aromatics are identified by capillary GC and GC/MS.

Nuclear Magnetic Resonance and Molecular Spectroscopies

Unlike chromatography and mass spectrometry, which can analyze components at a molecular level in a complex mixture, nuclear magnetic resonance (NMR) and molecular (IR and Raman) spectroscopies are used to determine the average structure of a mixture. However, the specific chemical shifts of functional groups in NMR and their unique vibrational frequencies in IR and Raman spectroscopies provide valuable information about their distribution in the mixture. For example, C-NMR has been used to effectively determine the content of aromatic and aliphatic carbons in diesel fuels.

Analysis of a representative diesel fuel by the methods described here shows that the main components of diesel fuels are saturated and aromatic hydrocarbons. The saturated hydrocarbons dominant in diesel fuels include normal paraffins, isoparaffins, and cycloparaffins (naphthenes). Normal paraffins have high cetane numbers and are desirable molecules in diesel fuels.
for combustion. High-boiling normal paraffins, however, cause cold-flow problems if present in excess. Other than isoprenoid hydrocarbons such as pristane and phytane, most of the isoparaffins in diesel fuels are mono- and dimethyl alkanes, predominantly with branch points near the ends of the alkyl backbone. The remaining saturated hydrocarbons are mainly 1-ring to 3-ring cycloparaffins. The 4- and 5-ring cycloparaffins, such as steranes and hopanes, are rarely present. Aromatic compounds are mainly benzenes, indans, tetralins, indenes, naphthalenes, biphenyls, acenaphthenes, fluorenes, acenaphthalenes, phenanthrenes, anthracenes, and naphthenophenanthenes. Diaromatic hydrocarbons are generally the most abundant aromatic components in diesel fuels. Trace amounts of PAHs (3- to 4-ring aromatic compounds) such as chrysene, pyrene, benzanthracenes, and perylenes can also be present.

The most common sulfur compounds are benzothiophenes and dibenzothiophenes. Trace amounts of nitrogen compounds include indoles, carbazoles, quinolines, acridines, and phenanthridines. The oxygen compounds most often reported in diesel fuels are phenols and dibenzofurans.

Formulated diesel fuels also contain small amounts of additives, such as cetane improvers, antioxidants, corrosion inhibitors, metal deactivators, dispersants, detergents, lubricity improvers, and cold-flow improvers, to improve storage stability and performance. Many physical and physico-chemical properties of diesel fuel are related to its composition. Linear regression and principal component analysis have been used for statistical analysis and correlation studies of chemical composition and physical characteristics (including cetane number and cetane index) of diesel fuels.\(^{(16-18)}\)

1 INTRODUCTION

The release of the Clean Air Act (CAA) Amendments of 1990 introduced reformulated gasoline legislation regulating the composition of fuels and particularly gasoline in order to improve the air quality by a significant reduction in vehicle exhaust emission levels. With the introduction of certain amounts of nonfuel oxygenates into fuel including various alcohols such as methanol, ethanol, tert-butanol and ethers like methyl tert-butyl ether (MTBE), ethyl tert-butyl ether (ETBE), tert-amyl methyl ether (TAME) and diisopropyl ether (DIPE) a reduction of carbon monoxide (CO) and unburned hydrocarbon emissions is envisaged. Furthermore, a reduction in aromatic compounds and benzene is demanded providing a decreased release of volatile organic compounds (VOCs).

With the implementation of this program, the refining industry and their petrochemical laboratories have been forced to control accurately and to monitor continuously their gasoline blending processes. Furthermore, regulatory agencies are required to implement the use of portable analytical techniques in order to ensure the enforcement of such novel threshold values.

Besides the conventional techniques using separation-based methods such as gas chromatography (GC), the mid-infrared (MIR) spectral range has gained significant importance. Owing to the molecule specific absorption patterns of ethers, alcohols and aromatics, the distinct determination of fuel additives and subsequent derivation of general fuel parameters is enabled. The performance of FTIR (Fourier transform infrared) and filter-based spectroscopic techniques will be reviewed and compared to other spectroscopic approaches. Furthermore, data evaluation procedures and ASTM (American Society for Testing and Materials) approval of these novel methods will be highlighted.

The release of the Clean Air Act (CAA) Amendments of 1990 introduced reformulated gasoline legislation regulating the composition of fuels and particularly gasoline in order to improve the air quality by a significant reduction in vehicle exhaust emission levels. With the introduction of certain amounts of nonfuel oxygenates into fuel including various alcohols such as methanol, ethanol, tert-butanol and ethers like methyl tert-butyl ether (MTBE), ethyl tert-butyl ether (ETBE), tert-amyl methyl ether (TAME) and diisopropyl ether (DIPE) a reduction of carbon monoxide (CO) and unburned hydrocarbon emissions is envisaged. Furthermore, a reduction in aromatic compounds and benzene is demanded providing a decreased release of volatile organic compounds (VOCs).
The standard determination method for such compounds is given in detail in section 2 and is based on gas chromatography with oxygen-selective flame ionization detection (GC/O-FID) as mandated by ASTM and USEPA (United States Environmental Protection Agency).\(^{(2,3)}\) The increasing demand claimed by regulatory agencies as well as petroleum companies for rapid and reliable analytical techniques capable of assessing these parameters in the field, has initiated the search for novel methods to supplement and possibly replace conventionally used separation techniques.

Infrared (IR) spectroscopy and particularly the MIR spectral range considered from 4000 to 400 cm\(^{-1}\) (2.5–25 µm) represents an analytical technique of constantly increasing importance. The introduction of rapid and powerful microprocessors enabling the implementation of fast Fourier transform calculation algorithms, especially, have established FTIR spectroscopy as one of the most commonly applied analytical methods since the late 1970s.\(^{(4)}\) While chromatographic techniques rely on the separation of the analyte molecules in the column in relation to their mass differences, IR spectroscopy enables the selective recognition of different species in relation to their specific molecular vibrations resulting in distinctive absorption bands in the corresponding spectral region. In contrast to NIR (near infrared) methods, MIR spectroscopy provides access to the comparatively strong fundamental vibrational modes of organic molecules, and individual fuel components can be differentiated by their characteristic pattern of absorption bands. Hence, the advantages of IR absorption spectroscopy compared to chromatographic systems particularly for a field applicable analytical method are evident: (i) usually no preparation of the sample is required, (ii) the potential exists for continuous operation providing on-line and real-time information because (iii) no preparation of the instrument prior to the measurement or after the determination is necessary, (iv) full analysis in typically less than 5 min, (v) the measurement and data evaluation procedure can be fully automated (chemometric methods), (vi) no extra trained personnel are needed.

Based on these considerations, several studies have proven that MIR FTIR spectroscopy is a versatile, efficient and accurate analytical technique for the determination of fuel additives and the estimation of key gasoline properties.\(^{(5)}\) Besides supporting the control and implementation of environmental regulations, an alternative tool for petroleum laboratories is provided, which could considerably increase the sample throughput, minimize the sample preparation and volume requirements and reduce the costs per sample compared to conventional analysis.

### 2 CONVENTIONAL FUEL PERFORMANCE SPECIFICATION

#### 2.1 Fuel Parameters and Properties

With respect to regulatory measures, the most important parameters of fuels which have to be addressed for sufficient fuel specification are listed in Table I. The particular substances of interest, which have to be measured selectively, are given in Table 2.

With the introduction of oxygenate additives for gasoline, a reduction of ambient CO by about 10% is envisaged. Reformulated gasoline will reduce VOCs and air toxics by approximately 15% requiring a content of at least 2 wt% oxygen and a maximum content of 1 wt% benzene.

Besides this positive environmental impact it is of major interest to investigate potential human health risks related to these new additives, especially MTBE as the most common representative of the oxygenates. Since MTBE is a widely used fuel blending component its environmental fate, especially in the aquatic groundwater phase, as well as its adverse human effects are currently the subject of intensive investigations with particular focus on long-term studies.\(^{(6)}\)

#### 2.2 United States Environmental Protection Agency Regulations

Gasoline and diesel fuel produced from petroleum (crude oil) power more than 95% of the combustion engine motored vehicle fleet in the USA. With the release

TBA, tertiary butyl alcohol.
of the CAA in 1990, strategies to reduce and prevent air pollution caused by vehicle exhaust emissions have refocused to emphasize improvements in fuel properties and thus fuel composition, rather than relying mainly on engine/vehicle emission control such as catalytic converters. This initiative led to provisions forcing modifications in the content in gasoline of nonpetroleum additives and, correspondingly, more stringent emission standards for combustion engines.

The pollution reduction programs implemented by the USEPA within the clean air legislation can be condensed into two main sections:\(^{(3)}\)

(i) Oxygenated fuels program: during the winter months from November 1 to March 1 gasolines sold in metropolitan areas defined as CO nonattainment zones have to contain at least 2.7% (w/w) oxygen.

(ii) Reformulated gasoline program: to reduce the ozone and smog levels gasolines available in nine extended city areas with most severe ozone pollution have to be reformulated in the first phase of this program, launched in the beginning of 1995, to an oxygen content of at least 2.0% (w/w). A reformulation of their contents of aromatics, benzene, heavy metals, sulfur and detergents is also included in the program.

With the implementation and compliance of these regulations, an increasing demand for the accurate determination of the oxygen content of fuels and for appropriate analytical techniques is obvious.

Currently applied standard methods for the determination of fuel components including oxygenates and aromatics mainly involve separation techniques such as GC/AED (atomic emission detection), GC/FID (flame ionization detection) and GC/MS (mass spectrometry).\(^{(7–9)}\)

3 MID-INFRARED SPECTROSCOPY FOR THE DETERMINATION OF FUEL PERFORMANCE SPECIFICATIONS

3.1 Short Introduction to Mid-infrared Spectroscopy

The MIR spectral range is generally considered to be from 4000 cm\(^{-1}\) to 400 cm\(^{-1}\) corresponding to 2.5–25 \(\mu\)m. Probing fuels and fuel mixtures with MIR radiation enables individual components to be detected and differentiated by their specific absorption pattern in this spectral region. Because the vibrational motions of the molecules occur at distinctive frequencies depending on their atomic masses, their relative bond strengths and their neighboring atoms and bonds, functional group assignment enables individual components to be distinguished in a fuel sample. This unique set of frequencies is directly associated with the molecular structure of the respective component and is represented in the so-called MIR spectrum of the analyte. Since MIR spectroscopy is based on the evaluation of the fundamental resonances, usually well-defined, sharp and specific absorption bands are available. The amplitude of the molecular vibrations is related to the concentration of the molecule within the sample and is represented in the peak height of an absorption spectrum. Since similar molecular structures partially result in absorption peaks located at the same frequency, the whole spectrum has to be evaluated for accurate data analysis.

The usefulness of applying MIR spectroscopy for fuel characterization becomes particularly evident when relating chemical gasoline features to the respective components influencing those properties.\(^{(10–12)}\) As an example, the octane number is strongly influenced by the aromatic hydrocarbon concentration: an increase in these components increases the octane number and simultaneously decreases the cetane number for diesel fuels. As detailed later, aromatic components such as benzene can be detected directly in the MIR region. The investigation of so-called oxygenated fuels especially is facilitated using MIR spectroscopic methods.\(^{(13)}\) Oxygen-containing fuel additives – mainly alcohols and ethers – improve the performance of combustion engines towards a more complete burning process thus reducing the CO emissions of vehicles by 15–20%. Because the characteristic C–O–H bonds of alcohols and the C–O–C bonds of ethers are represented by distinct absorption bands in the MIR region, analytical tools operating in that particular spectral region are of significant interest.

Examples of IR spectra of fuel additives are given in Figure 1 and demonstrate the suitability of detecting individual components using MIR spectroscopy as well as revealing the difficulty of differentiating between individual substances within a complex mixture.

Generally, the reported instrumentation can be divided into (i) FTIR spectrometer-based instruments that evaluate the whole spectral range using either attenuated total reflection (ATR) or micropath transmission cells, (ii) filter instruments that use a set of bandpass filters and a chopped light source to evaluate only the MIR spectral region of interest and (iii) hyphenated techniques that combine MIR spectroscopic detection with GC.

The most important techniques based on MIR spectroscopy, which can be applied to determine fuel specifications, are discussed below.

3.2 Fourier Transform Infrared-based Instrumentation

Various studies have shown that FTIR spectroscopy in the MIR region is the most versatile, efficient and accurate spectroscopic technique for the simultaneous assessment of key fuel parameters, because the whole spectral range
from 4000 to 400 cm$^{-1}$ can be used to gain molecule-specific information.

The main FTIR spectroscopic work on middle distillate fuels is focused on the direct investigation of gasoline properties, and particularly of regulated components such as benzene and oxygenates, as well as on deriving properties like the carbon/hydrogen ratio, aromatic hydrocarbon content, cetane index, refractive index, heat of combustion, viscosity and density. Particularly, in combination with multivariate (chemometric) data evaluation procedures, even derived values of gasoline properties such as the motor and research octane number (MON, RON), total aromatic, olefinic and saturated hydrocarbon content or total oxygen content are accessible.

In general, all methods collect an FTIR spectrum of a fuel sample in order subsequently to relate the resulting spectra either to a particular fuel additive/component or to a correspondingly selected fuel property value. Most methods involve additional multivariate (chemometric) data evaluation strategies enabling full automation of data processing, as well as the possibility of detecting the smallest changes in the IR spectrum.

Two main sampling techniques can be distinguished using either ATR or micropath transmission cells, the latter frequently combined with a flow injection analysis (FIA) arrangement for sample handling.

3.2.1 Fourier Transform Infrared/Attenuated Total Reflection

ATR has become a widespread sampling technique in FTIR analysis since the introduction of internal reflection spectroscopy (IRS) by Harrick in late 1960s. The evanescent field can be used to probe solid and liquid samples adjacent to the surface of a so-called ATR crystal, usually made from materials such as zinc selenide (ZnSe) or germanium (Ge). While circular ATR cells are also available, less expensive horizontal ATR configurations using conventional planar crystals with approximately 12 internal reflections are applied in the main, ensuring reproducible baselines and cross-contamination-free spectra following successive sampling. The top side of the ATR crystal is usually enclosed by a gasketed cover in order to reduce the evaporation and allow fuel samples to flush through as schematically illustrated in Figure 2a.

The penetration depth ($d_P$) of the IR radiation depends on the wavelength of the incident light ($\lambda$), the refractive indices of the waveguide ($n_1$) and the surrounding medium ($n_2$), $n_2 < n_1$ and on the angle of incidence ($\theta$), Equation (1)

$$d_P = \frac{\lambda}{2\pi n_1^2 \sin^2 \theta - n_2^2}$$

Typically, the penetration depth lies around 2 $\mu$m within the fingerprint region of the MIR range.

Following FTIR/ATR measurements evaluated with a partial least squares (PLS) spectral decomposition technique, Fodor et al. report reproducibility values for the
parameters listed in Table 1, including the boiling point at 50/90 vol% condensate and the end boiling point, that match or improve upon the ASTM reproducibility values of the respective standard procedures. Furthermore, the measurement time of a single sample could be reduced to 1 min and the sample volume reduced to 2 mL, attesting to the potential of FTIR/ATR measurements combined with multivariate data evaluation.

3.2.2 Fourier Transform Infrared/Transmission Cell

The use of inexpensive flow cells with a very small optical pathlength, typically between 0.1 and 0.015 mm, enables to determine the concentration of various fuel components by a simple transmission measurement as schematically depicted in Figure 2b. The windows of such cells are usually made from IR-transparent materials such as potassium bromide (KBr), calcium fluoride (CaF) or zinc selenide (ZnSe) providing access to a spectral range down to 400 cm$^{-1}$. Coupling such a measurement cell with an FIA system enables automated, simple and rapid sampling with the possibility of continuous monitoring.

Following the Lambert–Beer law, quantitative determination of fuel components is possible relating the absorbance ($A$) to the molar extinction coefficient ($\varepsilon$), the optical pathlength ($l$) and the concentration ($c$) by

$$A = \varepsilon cl$$  \hspace{1cm} (2)

Gallignani et al. report the detection limits of 0.02 vol% benzene with gasoline samples diluted 1:9 in hexane by

![Figure 2](image_url)
simply evaluating the peak height of the characteristic benzene absorption band at 675 cm\(^{-1}\).\(^{21}\) Coupling with a flow injection manifold ensures reproducible sampling and dilution conditions as demonstrated by comparison with results obtained by GC recommended as an ASTM reference method (D 3606-91). Owing to the miniaturized flow-cell the reagent consumption is kept at a minimum.

This method was later extended successfully to determine toluene (0.01–2.0 vol%) and MTBE (0.035–2.0 vol%).\(^{22,23}\) Using the same procedure, López-Anreus et al. demonstrated the possibility of determining benzene, toluene, and MTBE in gasoline after vaporization at 90°C and subsequent determination in an IR multiple pass gas cell in combination with a flow injection system.\(^{24}\)

### 3.3 Infrared Filter-based Instrumentation

Filter-based IR instruments utilize only selected bands of the MIR spectral range containing the absorption features of interest. The main advantage compared to FTIR spectroscopy using the information content of the whole spectrum can be seen in the considerably lower costs of the spectroscopic equipment. Owing to full automatization and compactness such instruments are ideally suited to on-site determination of fuel components.

Filter spectrometers use a simple light source emitting MIR radiation, such as a black body filament, which is modulated by a chopper or can be pulsed. The IR beam is guided through a sample cell with fixed optical pathlength, either in transmission or ATR configuration, to an appropriate IR detector, e.g. MCT (mercury cadmium telluride), DTGS (deuterated triglycine sulfate) or pyroelectric. Fixed frequency narrow bandpass filters usually mounted on a filter wheel are used to select the frequency range of interest.

All approved ASTM methods listed in section 3.6 involving MIR spectroscopy (except GC/FTIR coupling) allow the use of filter instruments as well as FTIR spectrometers.

### 3.4 Gas Chromatography/Fourier Transform Infrared

The application of the combination GC with FTIR for the determination of oxygenates in gasoline was mainly driven by the fact that conventional GC methods using O-FID or AED gave problems with the reliability or hydrocarbon interference.\(^{25,26}\) Primary chromatographic separation enables detection and resolution of impurities, for example, from the feed ethers during the blending procedure.

Within GC/FTIR the GC column is directly interfaced to the gas flow cell of an FTIR spectrometer using the so-called light pipe technique with a heated connection as indicated in Figure 2c.

Using selective absorbance reconstruction from the obtained IR spectra, results in a so-called selective absorbance (wavelength) chromatogram as an example are shown in Figure 3, with the most important components indicated as lines.\(^{27}\) The reconstruction frequency for each compound is determined by the absorbance maximum in the region of interest, \(\pm 4 \text{ cm}^{-1}\), using the C–O stretching region for alcohols and ethers and the aryl C–H out-of-plane bending region for aromatics, respectively.\(^{28,29}\) Thus, selectivity over coeluting hydrocarbons is achievable.

The separation shows sufficient resolution of all major compounds. ETBE and \(i\)-butyl alcohol can be separated more clearly by starting at a lower oven temperature and accepting an increased analysis time.

In conclusion, the combination of GC and FTIR yields good selectivity over hydrocarbons for \(C_1–C_4\) alcohols and \(C_3/C_5\) ethers using appropriate absorbance reconstruction frequencies. Diehl et al. have extended the applicable range of GC/FTIR to the quantification of BTEX (benzene, toluene, ethylbenzene, xylene) and 25 individual aromatic hydrocarbons, which presents an alternative method to the ASTM method D 3606 for benzene, in respect of the proposed ASTM approach using GC/MS for the determination of the aromatics.\(^{30,31}\)

Since 1996 GC/FTIR has been approved as an ASTM standard (D 5986) as detailed in section 3.6.2.

![Figure 3 Schematic selective absorbance (wavelength) chromatogram from 1250–1000 cm\(^{-1}\) of 1 vol% of typical additives in gasoline. 1,2-Dimethoxyethane serves as internal standard.\(^{11}\) The unlabeled peaks represent hydrocarbons. 1, methanol; 2, ethanol; 3, 2-propanol; 4, \(i\)-butanol; 5, 1-propanol; 6, methyl-\(i\)-butylether; 7, 2-butanol; 8, disisopropyl ether; 9, \(i\)-butanol; 10, ethyl-\(i\)-butylether; 11, 1,2-dimethoxyethane; 12, 1-butanol; 13, \(t\)-amyl-methylether.](image-url)
3.5 Chemometrics

The majority of methods presented here take advantage of the exceptionally high information content of IR spectra in the range of 4000–600 cm⁻¹, without including methods combined with separation techniques. Using these, data fuel quality properties such as initial/ final boiling point, density, viscosity, aromatic and oxygenates content, and so on can be predicted. In order to gain sufficient accuracy from these measurements, so-called chemometric data evaluation methods have turned out to be a valuable tool supporting data interpretation and automated evaluation of the spectra obtained.

Commonly, these methods require a set of calibration samples to train the system using their IR spectra, which are usually mean centered beforehand. Subsequently, an external set of new test samples is necessary, which has to be uncorrelated with the calibration set, in order to assess the capabilities of the respective multivariate data evaluation method. As a measure of the quality of the prediction provided by the model, the standard error of prediction (SEP) is generally used.

The most commonly applied chemometric methods involve multiple linear regression (MLR), PLS methods or principal components regression (PCR), which are outlined below.

The best results with respect to SEP, precision, repeatability and reproducibility have been found for PLS treatment of IR spectroscopic data, which makes this data evaluation procedure most adequate for routine implementation in combination with IR techniques.

3.5.1 Multiple Linear Regression

MLR determines the combination of independent prediction variables, which shows the best reproduction of the so-called dependent variables. The criterion used for selection of the best fit is generally the least squares criterion, resulting in a multiple linear correlation coefficient or the percentage of fit. The limitation of this technique can be seen in the problem of ensuring that all prediction variables are independent, because otherwise problems occur when entering the regression step.

A possible solution to this problem with respect to spectroscopic data is to apply methods, which remove a variable from and enter a variable into the set of prediction variables in a stepwise fashion, since both do not necessarily result in the same final set.

3.5.2 Principal Components Regression

PCR avoids redundant information by selecting only the primary dimension of information, the so-called variance, which is fitted by regression to the prediction variables. Irrelevant information, such as the noise in spectral data, remains in the final principal components, because only the primary principal components are usually fed stepwise into the regression model. In contrast to MLR, collinearity is avoided since principal components are respectively orthogonal. However, because the last principal components are not considered, the uncertainty remains that useful information for the prediction might be lost.

3.5.3 Partial Least Squares

PLS is probably the most interesting tool for evaluating spectroscopic data for fuel property prediction. With this so-called canonical regression, the degree of relationship between a set of prediction variables and a set of resulting variables is determined. All the information from each source which is relevant to both sets of variables and avoids unrelated information is used, selecting the data by their predictive ability. Hence, frequent cross-validation is necessary to optimize and finally to select the PLS model with the best predictive characteristics.

Owing to achievable SEP, precision, repeatability and reproducibility, PLS treatment of IR spectroscopic data is the most useful chemometric method of automated data interpretation in order to yield standard fuel properties.

3.6 Mid-infrared Spectroscopy-based American Society for Testing and Materials Methods for Fuel Characterization

The acknowledgment of several IR-based methods for the determination of oxygenates and aromatics in fuels by ASTM attests to the fact that spectroscopic methods are gaining increasing importance in this area. The main advantages of these methods can be summarized as being cost effective, simple to run, portable and considerably faster than currently used systems.

3.6.1 Standard Test Method for the Determination of Oxygenates in Gasoline by Infrared Spectroscopy (D 5845-95)

This approved standard method covers the determination of various oxygenates in gasoline (see Table 3) using either a transmission cell or an ATR configuration combined either with a filter-based MIR system, an FTIR spectrometer or a dispersive MIR apparatus.

Generally, the sample is introduced into a liquid sampling cell as shown schematically in Figure 2 and a beam of MIR radiation is imaged through the sample onto an appropriate detector. The spectral region used for data evaluation is either selected mathematically after recording a whole spectrum or in case of filter-based instruments by highly selective bandpass filters. Subsequent multivariate data analysis allows calculation of the concentration of the components of interest.
The driving force behind the introduction of MIR spectroscopy as standard method is the fact that it is comparably faster, simpler, less expensive and more portable than currently used methods based on GC. Although this test method is not approved for testing for compliance with federal regulations, it applies well to quality control especially in the production of gasoline.

### 3.6.2 Standard Test Method for the Determination of Oxygenates and Aromatics in Finished Gasoline by Gas Chromatography/Fourier Transform Infrared Spectroscopy (D 5986-96)

Using this test method the quantitative determination of oxygenates and aromatics (see Table 4) in finished gasoline is enabled by combining GC with FTIR spectroscopy via a so-called light-pipe system as depicted schematically in Figure 2c.

This method utilizes a methylsila-wall-coated open tubular (WCOT) GC column interfaced to an FTIR spectrometer via a light pipe, enabling the compounds of interest to be detected by their characteristic absorption bands after separation in the column.

</tbody>
</table>

This method enables testing for oxygenates and aromatics simultaneously, without interference, for quality control and fuel regulation surveys. However, expensive equipment is mandatory owing to the hyphenation of two analytical techniques and the portability is limited.

### 3.6.3 Standard Test Method for the Determination of Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy (D 4053-98)

With this method the percentage of benzene in full-range gasoline can be assessed in the concentration range from 0.1–5 vol%.

Using a thin film absorption flow cell that enables transmission measurements, benzene can be determined following a correction for interference with heavier aromatic compounds and comparison with calibration blends of known benzene concentration.

### 3.6.4 Standard Test Method for the Determination of Benzene in Spark-ignition Engine Fuels using Mid-infrared Spectroscopy (D 6277-99)

This ASTM method covers the determination of the percentage of benzene in spark-ignition engine fuels addressing a concentration range of 0.1–5 vol%. Again, a liquid sample cell is applied using either an ATR or transmission cell configuration in combination with an FTIR spectrometer or a filter-based system.

This simple method enables rapid and simple detection of benzene in fuels at low cost and can be applied for quality control in the production of spark-ignition engine fuels.

### 3.7 Comparison with Other Spectroscopic Techniques

Apart from FTIR spectroscopy in the MIR region, several studies describe the application of NIR spectroscopy (0.9–2.5 µm) to the determination of gasoline and middle distillate fuel properties. Furthermore, Fourier transform Raman spectroscopic methods have been used to investigate fuel specifications.

An NIR spectrum generally results from overtone vibrations and combination tones of the fundamental molecular vibrations occurring in the MIR spectral range and can be considered to be up to a factor of 1000 weaker than the associated absorption band at the fundamental frequency. In contrast to the MIR region, usually broad and overlapping absorption bands have to be evaluated applying chemometric data evaluation almost exclusively. The combination of NIR spectroscopy with optical fibers enables such analysis systems to operate remotely and on-line without sample preparation, as shown for determination of MTBE in gasolines. Owing to developments in the field of MIR fiber optic sensors it
can be expected that this extension of MIR spectroscopy will be available for gasoline analysis in the near future.

Raman spectroscopy is generally a method well-suited to hydrocarbon analysis. Owing to the strong fluorescence of gasoline samples, dispersive Raman spectroscopy using a visible light source cannot be applied. Alternatively, Fourier transform Raman using an NIR laser, usually Nd:YAG at 1.06 µm, is well suited, because the fluorescence background caused by e.g. aromatics is sufficiently reduced. Fiberoptic Raman spectroscopy has been applied to characterizing petroleum products, determining RON, MON, density and the benzene content following a PLS data evaluation approach. Although appropriate for fuel analysis Fourier transform Raman spectroscopy is still not widely used because of the cost of equipment, which is not yet routinely used or established in petroleum laboratories and controlling agencies.

A special application of NIR as well as Raman spectroscopy is reported by Choquette et al., who show the application of these methods to determine oxygenates in gasoline standard reference material (SRM) as provided, e.g. by NIST (National Institute of Standards and Technology). Since these SRMs are provided in sealed glass ampules, MIR spectroscopy cannot be used since these ampules are not transparent in the MIR spectral range. Both techniques have proven to be feasible for identifying the additives MTBE, ETBE, TAME and EtOH and for quantifying the oxygen concentration to an accuracy within 0.1% oxygen mass fraction in less than 1 min. Cooper et al. conclude in a comparison of MIR, NIR and Raman spectroscopy that particularly for the detection of MTBE in gasoline, MIR spectroscopy is the method of choice because of the distinct absorption pattern and pronounced absorption bands, especially in the fingerprint region.

5 CONCLUSIONS

Owing to the developments in the field of MIR spectroscopy and the increasing demand for fuel properties to be determined by simple, accurate and portable techniques, novel systems have been established for the direct measurement of fuel additives, taking advantage of the specificity of molecular vibrations in the MIR spectral region. Apart from sum parameters such as oxygenates, aromatic and olefinic hydrocarbon content, selected compounds such as ethers, alcohols and benzene can be measured directly using MIR spectroscopic techniques in combination with microflow cells or ATR configurations. With the possible assessment of distinct analytes, general fuel parameters such as the octane number or physical properties can be derived applying chemometric data evaluation techniques.

Considering ASTM approvals, the wide range of applications and the commercial availability of compact and rugged MIR spectroscopic instruments at a competitive price it can be assumed that MIR spectroscopy for the determination of fuel performance characteristics will be established as a routine method in a wide range of applications in the petroleum industry as well as by regulatory agencies.

This article provides a general survey of the chemical and physical analyses of light and mid-range hydrocarbon...
fuels needed to satisfy the environmental and safety requirements of the refining and transport industries. Since the inception of the oil and automobile industries, emissions from vehicles and from fuel refineries have taken a back seat to the performance factors of the fuels themselves. In the middle of the 1900s, new environmental requirements became a commercial consideration as governments, and to a lesser extent, industrial consortia, began to impose requirements on the fuels which had little or nothing to do with performance in the engine. This article will attempt to enumerate the most prevalent of these testing specifications and provide a modest amount of information about what they involve and why they exist. At the time the original draft of this work was written in 1999, the imposition of several new regulatory criteria in the United States had just been imposed on most of the fuels production companies. Few new regulations have been enacted in the last few years (1995+) prior to this article’s printing, but there have been numerous serious proposals for such new legislation and several more geographical areas have come under existing and more stringent legislation. We have tried to assess where future regulations will lead and what specifications and tests might deal with these limits.

In general, we will not deal here with the engine performance specifications. These are detailed far more adequately elsewhere in the literature. This article will not provide a long treatise on the formulation of transportation fuel manufacturing processes, and neither will it delve deeply into the testing methodology. Enough of these three subjects will be presented to allow the reader to put the regulatory specifications and what they entail into perspective. The emphasis is slanted towards the specification of gasoline range fuels, primarily caused by the great predominance of these commodities, but we do try to cover the heavier transport fuels in detail as well. There is considerable overlap in several of the specifications, at least in terms of methodology, even if the specification document number perhaps differs from light to heavier fuels.

The various testing specifications are presented by a fairly succinct description and are categorized by test type and by species analysis requirements. An attached glossary will enable the reader to become acquainted with the jargon of emissions compliance and refinery technology, since these are both linked to intelligent discussion of fuels production and usage.

1 INTRODUCTION

Within the United States, about 60% of every barrel of crude oil processed in a typical refinery is converted into motor gasoline and another 15% into alternative transportation fuels such as jet fuel, turbine fuel and diesel fuel.\(^{(1-3)}\) Performance quality and contractual specification standards are many and exacting for the final product as it is carried to the retail market. These standards have been defined by more than 80 years of testing and experimentation on all kinds of combustion engines in all sorts of worldwide climatological and geographical environs.

This article is not about these types of standards. They are described elsewhere in the technical literature in great and accurate detail. They are mentioned here in passing only to remind ourselves that in spite of all other requirements imposed on the transportation fuel markets by regulatory agencies, the major reason for these fuels to exist is their ability to meet the specifications for modern high performance internal combustion (IC) engines. Neither is this article a detailed report about the process of making environmentally friendly fuels. Enough of this topic is presented here to allow the reader to place the types and needs of various analyses and tests within the proper context of a modern refinery but much on this subject will be missing and for a full treatise on the gasoline manufacturing process, the reader would best be served by other references.

What will be attempted here is to provide a general survey of the chemical and physical analyses of light and mid-range hydrocarbon fuels needed to satisfy the environmental and safety requirements of the refining and transport industries. Since the inception of the oil and automobile industries, emissions from cars and from fuel refineries took a back seat to the performance factors of the fuels themselves. In the mid-1960s, however, as many cities worldwide began to choke on combustion-derived air pollutants, new requirements became a part of the commercial scene as governments, and to a lesser extent, industrial consortia, began to impose requirements on the fuels which had little or nothing to do with performance in the engine.

The appropriate analytical procedures for detecting regulated chemical quantities in the laboratory and online in the manufacturing process will also be covered. This will not be a comprehensive manual on the analysis procedures themselves. It will not, for example, describe how to run a gas chromatograph or fluorescent indicator absorption (FIA) unit in great detail. This information, again, is well detailed in the literature and readily available to the laboratory and control instrumentation engineers and technicians who design, install, run and maintain this type of equipment. Certain exceptions will be made, to the extent of making important caveats known or of providing a specific emphasis directly related to the analytical need at hand.

The major emphasis will be on the regulatory analysis requirements for gasolines but also discussed will be jet/
turbine and diesel fuels, for completeness of coverage. As a rule, the lighter the molecular weight or gravity of the liquid, the more and easier will be the analytical choices. The heavier the fuel, the fewer simple methods are feasible.

Sections 2 through 5 will cover background and related material. It is important to consider these topics when performing analyses for control of regulatory components in fuels. The fuels must be sold so the performance characteristics must be considered, even when they are not necessarily the controlling factors in the blend as perhaps they once were. Section 6 will discuss the methodology of testing. There are numerous techniques available to the laboratory analyst and the on-line instrument designer. Most give adequate results; some give better results in one circumstance and worse in others. Where applicable such discrepancies and caveats will be mentioned. Section 7 presents the myriad of available standards and specifications that cover the realm of regulatory analysis requirements. The great emphasis will be on the American Society for Testing and Materials (ASTM) standards with several American National Standards Institute (ANSI) and International Standards Organization (ISO) standards mentioned as well. These compose 95% of the world’s governing standards at this time and are usually in agreement with one another on most matters. Thus we give them emphasis, rather than unintentionally exclude any other local standards that may apply. This work is completed with a glossary of commonly used terms, that might be encountered in the fuels regulation world with emphasis on governmental acronyms, technical terms, and consortia and trade association abbreviations.

References to these three organizations and their publications of interest will not be listed as the mention of each standard is fairly obvious. The reader should note that revisions to each standard are issued on a fairly regular basis, if not each year. Thus the inclusion of specific yearly issue dates has been omitted and the reader must take care to obtain the latest version from each organization.

2 THE REGULATORY LEGACY FOR PETROLEUM FUELS

2.1 History of Fuels Formulations

Fuel driven engines of any sophistication have been available only since the mid-1880s. Several early prototypes were indirect drive – the Stanley steamer, for example – and could theoretically use any type of combustible fuel such as coal or wood. By 1890, however, the IC engine won the battle for acceptance.

At this time the most suitable fuels for the automobile were either coal tar distillates or the lighter fractions from the distillation of crude oil. During the early 20th century, oil companies were producing gasoline as a simple petroleum distillate (“white oil”) without benefit of stabilization (removal of butanes and lighter components). Automotive engines before long were rapidly being improved and required a more suitable fuel. During the 1910s, laws prohibited the storage of these unstable gasolines on residential properties, so several automotive manufacturers modified IC engines to run on kerosine. However, the kerosine-fueled engine would “knock” and crack the cylinder head and pistons. Research at the time demonstrated that the knock was caused by a rapid rise in pressure after ignition, not during preignition as then believed. This lead to the search for several types of antiknock agents, culminating in the common usage of tetraethyl lead for this purpose. Typical mid-1920s gasolines were 40–60 octane.

By the 1930s, the petroleum industry had determined that the larger hydrocarbon molecules (kerosine) had major adverse effects on the octane of gasoline, and were developing consistent specifications for desired properties. In the 1940s, catalytic cracking processes were introduced, and gasoline compositions became fairly consistent between brands during the various seasons.

The development of the alkyl leads (tetramethyl lead, tetraethyl lead) and the toxic halogenated scavengers (to keep the lead from plating out on valves and piston seats) meant that petroleum refineries could configure their refineries to produce hydrocarbon streams that would increase octane with small quantities of alkyl lead.(5-8) By adding increasing amounts of alkyl lead compounds, the lead response (positive octane increase) of the gasoline decreases, and so there are economic limits to how much lead should be added. The 1950s saw an increase in the cylinder compression ratios,(9) requiring even higher octane fuels. Lead levels were increased, and some new refining processes (such as hydrocracking), were specifically designed to provide hydrocarbons components with good lead response and octane.(10)

Well into the late 1960s, alkyl leads were added to gasolines for octane boost. The upper limit was 1.14 g Pb L⁻¹, which is well above the “diminishing returns” part of the lead response curve for most refinery streams. It is unlikely that much fuel was ever made at that level. Published articles on the subject usually set 1.05 g Pb L⁻¹ as about the economic maximum, and other literature suggests that 1970 100 research octane number (RON) premiums had about 0.7–0.8 g Pb L⁻¹ and 94 RON regulars 0.6–0.7 g Pb L⁻¹, which matches published lead response data.

Table 1 shows the typical lead response of two basic refinery blend stocks.

Except for the lead technology and the introduction of saturated hydrocracked and alkylated stocks, only minor improvements were made for several years to basic gasoline formulations. The bulk of the automotive research effort was applied to engine design and performance optimization. Most fuel changes were implemented primarily to improve yields and octane, until the 1970s, when unleaded fuels were introduced to protect the exhaust catalysts that were also being introduced for environmental reasons. From 1970 until 1990, gasolines and corresponding refinery processes were slowly changed as lead was phased out. In 1990 the Clean Air Act (CAA) started forcing major and more rapid compositional changes in gasoline. These changes will continue into the 21st century because gasoline combustion is and will still be a major air pollution source. The toxicity of the alkyl lead components and the halogenated scavengers became of increasing concern, alternatives were considered. The most famous of these is methycyclopentadienyl manganese tricarbonyl (MMT), which was used in the US until banned by the United States Environmental Protection Agency (US EPA) in 1978, but is approved for use in Canada and Australia until the year 2000. It is more expensive than alkyl lead and has been reported to increase unburned hydrocarbon emissions and block exhaust catalysts. Other compounds that enhance octane have been suggested, but usually have significant problems such as toxicity, cost, increased engine wear, etc. Other such compounds include dicyclopentadienyl iron and nickel carbonyl.

Kerosine cuts have had far less change than gasolines, at least in terms of postproduction processing. Most of them are still taken from “straight run” streams and perhaps stabilized (redistillation) to reduce flash point for storage reasons. Though they briefly had a fling as spark engine fuels, the lighter gasoline stocks quickly took over this role. Kerosine was relegated to lamps, camp stoves, smudge pots, and to a few “spray type” furnaces using aerosol-forming burners. With the widespread introduction of turbine-type engines in the late 1940s, this cut became a favorite economic fuel, especially for jet engines. The product specifications for kerosine/jet/turbine fuels became more exacting but still less complex than those of gasoline.

Diesel fuel stocks vary somewhat according to their gravity but are still produced from crude unit distillation and, since the late 1960s, from hydrocracker units. Because the compression–ignition (CI) cycle engines that they serve are far less complicated in terms of combustion initiation, less is expected of this refinery product’s specification, primarily the removal of light naphtha from the front end of the distillation curve, the cloud point (for cold weather nascent wax solidification) and pour point concerns and its cetane index, diesel’s analog to gasoline octane for ignition control. The relative volume usage of diesel in the commercial market is determined by heavy truck and rail needs. Advances in engine size reduction as well as in sheer numbers of these engines in the transport sector stimulated the diesel supply chain to create an expansion in mid-distillate demand. This demand was prompted by use in several diesel-fueled models of passenger cars as a response to the political disruptions in the gasoline fuel supply in the 1970s. This latter market demand factor was quickly attenuated by the 1980s environmental regulatory sector which objected to the aromatics and particulate contents of diesel engine emissions.

2.2 History of Fuels Emissions Reductions

With the widespread post-World War II deployment of gasoline-driven automobiles, kerosine-driven jets, turbine-drive generators, and diesel-powered trucks and trains, the types and levels of fuel combustion by-products began to affect the quality of life in several areas of the developed world. Such pollutant emissions were most notable where the combustion engine was most concentrated, in large urban areas.

Cars emit several pollutants as combustion products from the tailpipe (tailpipe or exhaust emissions), and as losses due to evaporation (evaporative emissions, refueling emissions). The volatile organic carbon (VOC) emissions from these sources, along with nitrogen oxides (NOx) emissions from the tailpipe, will react in the presence of ultraviolet (UV) light (wavelengths of less than 430 nm) to form ground-level (tropospheric) ozone, which is one of the major components of photochemical smog.

Smog has been a major pollution problem ever since coal-fired power stations were developed and domestic trash (rubbish) burns were permitted in urban areas, but these emissions were the first to be addressed and reduced...
in the early 1960s. Tailpipe and crankcase emissions were responsible for the majority of ozone-forming pollutants in the late 1960s. Ozone levels in the Los Angeles basin, as a significant example, reached 450–500 ppb in the early 1970s, well above the typical background of 30–50 ppb.\(^\text{18}\)

The first of several air pollution control acts was passed by the US Congress in 1962. While its emphasis was on industrial smokestacks and trash incinerators, the principle of government control of emissions was established and the formation of several urban and state coordinated “smog centers” were given legal and financial encouragement.

The CAA of 1990, now administered by the US EPA, is the primary statute governing air quality in the United States. It has been amended several times since it was first enacted in 1967. Initially, the CAA focused on vehicle-related controls, such as exhaust catalytic converters, exhaust gas recirculation (EGR), and crankcase carbon adsorption canisters to reduce ozone-forming (NO\(_x\)) and unburned hydrocarbons and carbon monoxide emissions from automobiles.

The automotive manufacturing industry responded with major advances in emission control technology.\(^\text{19}\) The total challenges involved were significant. The design of the engine can have very significant effects on the type and quantity of pollutants. Unburned hydrocarbons in the exhaust originate mainly from combustion chamber crevices, such as the gap between the piston and cylinder wall, where the combustion flame cannot completely use the hydrocarbons. The type and amount of unburned hydrocarbons are related to the fuel composition (volatility, olefins, aromatics, final boiling point (FBP)), as well as state of tune, engine condition, and age/condition of the engine lubricating oil.

It soon became apparent that major design changes to the typical automobile engine could no longer be avoided. Tuning a carbureted engine, for example, has only a marginal effect on pollutant levels. More was required, so exhaust catalysts were offered as a postengine solution that could ensure pollutants were oxidized. As engine management systems and fuel injection systems have developed and become more sophisticated, the volatility properties of the gasoline have been tuned to minimize evaporative emissions yet maintain low-exhaust emissions. Since the late 1970s, gasoline vehicle emission rates have been cut by about 80%. Overall vehicle emissions will continue to drop each year as older cars are replaced by newer ones.\(^\text{20–22}\)

Because leaded antiknock compounds were found to destroy the performance of catalytic converters then under development, US passenger car manufacturers in 1971 began to build engines designed to operate satisfactorily on gasolines of nominal 91 RON. Some of these engines were designed to operate on unleaded fuel, while others required leaded fuel or the occasional use of leaded fuel. The 91 RON was chosen in the belief that enough unleaded gasoline at this level could be made available in the current refinery base.

Beginning with the 1975 model year, most new car models were equipped with catalytic exhaust treatment devices in addition to all the previously mentioned crankcase emissions control technology. The need for gasolines that would not adversely affect such catalytic devices has led to the large-scale availability and growing use of unleaded gasolines.

There was a further reason why alkyl lead compounds were subsequently reduced, and this was the growing recognition of the potentially toxic nature of the emissions from a leaded gasoline-fueled engine. Not only were toxic lead emissions produced, but the added lead scavengers (ethylene dibromide and ethylene dichloride) could react with hydrocarbons to produce toxic organohalogen emissions such as dioxin. Even if catalysts were removed, or lead-tolerant catalysts discovered, alkyl lead compounds would most likely remain banned because of their toxicity and toxic emissions.

### 2.3 History of Reformulated Fuels\(^\text{11,12,15,17,20,23–25}\)

In spite of the emissions control advances, air quality did not improve enough in certain metropolitan areas where the impact of emissions was severe. Lead removal itself did nothing to improve air emissions control, it just kept the catalytic converters working longer. The US Congress turned to fuel formulation changes as another means of reducing emissions. As tailpipe emissions were reduced by the use of improved exhaust emission control systems, the hydrocarbons produced by evaporation of the gasoline during distribution, vehicle refueling, and from the vehicle, become more and more significant. A recent European study found that 40% of artificial VOCs came from vehicles. Many of the problem hydrocarbons are, unfortunately, aromatics and olefins that have relatively high octane values. Removing them in major quantities presented some major changes in the gasoline pool that resulted in potential engine performance problems.\(^\text{26}\)

The CAA Amendments of 1991\(^\text{13,27,28}\) required the US EPA to adopt regulations for reformulated gasolines (RFGs) in the USAs nine worst ozone nonattainment areas. (“Nonattainment areas” are areas which do not meet one or more of the air quality standards established by the US EPA.) If they choose, less severe ozone nonattainment areas across the USA have the option to participate in the Federal RFG program. To date, the US EPA has received participation requests from several states, primarily in the northeast USA, and the District
of Columbia. Other less severe ozone nonattainment areas have adopted other approaches, such as limiting gasoline vapor pressure as a more cost-effective means of improving air quality. Almost every state and major metropolitan area in the United States now has its own air quality management district (AQMD).

The program requires numerous changes in fuel constituents to reduce ozone-forming hydrocarbons and toxic constituents in air. Toxic air constituents, as defined in the CAA, are benzene, butadiene, formaldehyde, acetaldehyde, and polycyclic organic matter. The US EPA has established specific limits for some of these changes. For others, the US EPA developed the emissions reduction schedule summarized in Table 2. The goals will be implemented in two phases to mitigate the effect of the necessary processing changes on the petroleum industry. Similar European Union (EU) protocols are given in Table 3.

Phase 1 (begun on January 1, 1995) is required to achieve a reduction of 15–17% of ozone-reforming hydrocarbons during the high-ozone season and an annual reduction of 15–25% of air toxic emissions from vehicles fueled with RFG. For example, with methyl tertiary butyl ether (MTBE)–RFG, benzene and butadiene emissions decrease, whereas formaldehyde and MTBE emissions increase, all within the context of a net decrease in hydrocarbons.

Phase 2, which began January 1, 2000 (except in highly noncompliant areas such as California where it has been law since 1996) is required for most of the US to achieve an annual reduction of 25–29% in ozone-forming hydrocarbon emissions, a 5–7% reduction in ozone-reforming nitrogen oxide emissions, and a 20–22% reduction in air toxic emissions. The US EPA gives refinery planners the option of meeting a “per

a Recent revisions to these codes have allowed for seasonality. The EN228 standard now controls RVP. EU, European Union.
gallon” standard or an “averaged” standard; in the latter case, the refiner measures the average values of their annual production against the limits. US EPA also provided two emissions level calculations (simple and complex models) to determine the levels of criteria pollutants that a particular refiner’s sales block will generate.

The simple and complex models$^{28,29}$ are collections of equations and specifications which relate the emissions produced by a specific batch of gasoline, when it is used in a typical vehicle, to its composition and properties. As the names suggest, the simple model involves fewer gasoline properties than the complex model. The models are the mechanism which provides formulation flexibility to refiners, while ensuring that they meet the emission goals. The models are based on measured emissions from a variety of vehicles for a range of gasolines with different properties and/or compositions. Since different vehicles emit different amounts of pollutants, the result obtained by applying the model is an average for the total vehicle population. In 1998, most US refiners were required to use the complex model. In the three-year period 1995–1997, refiners were allowed to use either model.

As well as the US EPA requirements mentioned in this section, there are various restrictions introduced by the CAA and state bodies such as the CARB that often have more stringent limits for the above properties, as well as additional limits. The CAA specifies that some regions that exceed air quality standards had to use RFGs all year, starting January 1995. Other regions were required to use oxygenated gasolines for four winter months, beginning November 1992. The RFGs also contain oxygenates. Metropolitan regions with severe ozone air quality problems were required to use RFGs in 1995 that contain at least 2.0 wt% oxygen, reduce 1990 VOC compounds by 15%, and reduce specified toxic emissions, first by 15% (1995), then 25% (2000). Metropolitan regions that exceeded carbon monoxide limits were required to use gasolines with 2.7 wt% oxygen during winter months, starting in 1992.

Because phosphorus adversely affects exhaust catalysts, the 1990 US EPA regulations also limited phosphorus in all gasolines to 0.0013 g Pb L$^{-1}$, in effect making this a criteria fuels component as well.$^{22}$

Sulfur compliance is currently (1999) around 350 ppm, well above Phase II specifications. In some regions, the average emissions are nearer 500 ppm. Large refiners will have to meet CARB-like specifications by 2004 and smaller refiners between 2006 and 2010 depending upon which piece of legislation is consulted.

California, the birthplace of RFG, is now planning to ban methyl tertiary butyl ether (MTBE)$^{30}$ as a danger to groundwater supplies. Unfortunately, no alternative “official” specification replaces it, and the matter currently resides in several court venues.

### 2.4 Regulatory Requirements for Diesel Fuels

As is the case with many environmental requirements relating to vehicular emissions, diesel fuel specifications had their origin in California and are most stringent there. There is also a likelihood that any fuel specifications begun in California may eventually spread to the remainder of the United States and might also come to Europe. It is therefore logical that any discussion regarding trends in diesel fuel specifications should start with those in California.

Particulate emissions, especially the size fraction smaller than 10 μm, are also drawing attention as a serious health concern. The current major source is from (CI = diesel) engines, while the modern spark ignition engine system has no problem meeting regulatory requirements.

#### 2.4.1 California Specifications

The most exhaustive legislation regarding diesel fuel specifications is in place in California,$^{31}$ enacted by the California Air Resources Board (CARB). A summary of this legislation is shown in Table 4 below. The legislation affects both the sulfur content and aromatics level of diesel fuels.

The sulfur requirement for diesel fuels is 500 ppm maximum. The sulfur restriction is based on the one to one correlation of fuel sulfur content with sulfate particulate emissions. All refiners in the south coast air quality district (Los Angeles basin) have faced this sulfur requirement since 1985.

The aromatics requirement is 10% maximum for large refiners and 20% maximum for small refiners.

### Table 4 CARB diesel fuel reformulation requirements effective October 1993

<table>
<thead>

<td>40</td>
<td>40</td>
<td>40</td>
</tr>
</tbody>
</table>

$^a$ The 0.50 value is the ASTM specification for #2 diesel. Most production is typically about 0.30 maximum. Since 1985, sulfur specification in the Los Angeles Basin has been 0.05 weight% max.

$^b$ Small refiners had until October 1994 to implement sulfur specifications.

$^c$ CN (cetane number) is not a legislated specification but is based on ASTM standards for #2 diesel fuel.
There has been much controversy over the aromatics requirement. The principle behind the aromatics restriction is to reduce NO\textsubscript{x} and particulate emissions. The Coordinating Research Council (USA) (CRC), a joint industry group, has conducted a number of studies attempting to relate diesel emissions to fuel properties. Their summary report concluded that there was a significant correlation of emissions with fuel aromatics content. The correlation held for most types of emissions, including hydrocarbons, NO\textsubscript{x}, CO, and particulates. This test program primarily utilized neat (no additive) fuels and no correlations were developed to relate emissions to CN. Subsequent studies that have included fuels with and without cetane improver have shown a much better correlation of emissions with fuel CN. Despite these arguments, the aromatics specification has remained in place. The earlier reported small degree of positive correlation of emissions versus aromatics has been sufficient to maintain the requirements.

Compounding the situation is the method specified by CARB for measuring aromatics. CARB has specified the fluorescent indicator absorption (FIA) test, ASTM D-1319, as the method for determining aromatics. This test is not applicable for many higher boiling diesel fuels. As yet there has been no change in this test specification. There have been a number of papers that have discussed various methods for determining diesel fuel aromatics.\(^{(32,33)}\)

There is one option for a refiner to bypass this maximum aromatics requirement. CARB has defined the properties of a reference diesel fuel. This fuel must be derived from straight-run diesel stocks from crude oils that are typically run in California refineries. The reference fuel must then meet the requirements shown in Table 5. The key parts to these requirements are the 10% aromatics requirement and the relatively high natural CN of 48. In order to qualify as an alternative fuel, a specific side-by-side emissions test is performed with the reference fuel and the alternative fuel. If the alternative fuel emissions meet or better those of the reference fuel, the alternative fuel can be qualified. Certain properties of the alternative fuel then become new specifications for that refiner. These properties are also noted on Table 5. While many California refineries are pursuing this option, it still may involve a tightening of specifications. Some estimates indicate that a qualifying alternative fuel may require an aromatics content of 15–25% and a CN in the range of 48 to 52.

One major southern California refiner claims to have a new clean diesel fuel that will surpass Phase II limits, provide higher cetane, reduce NO\textsubscript{x} emissions by 5% and reduce particulates by 15%. If true, this may become the future specifications for RFG.

### 2.4.2 United States Environmental Protection Agency Diesel Fuel Specifications

These specifications include the lower sulfur requirement of 0.05 weight% maximum. Rather than an aromatics specification, the US EPA has proposed a minimum cetane index of 40. This type of specification is thought to be more reasonable with respect to emissions control. Current ASTM specifications for Number 2 Diesel call for a minimum CN of 40. Thus, unless a refiner is using a lot

of cetane improver, the cetane index specifications will not be a significant change. It could have an impact on refiners who use large quantities of fluid catalytic cracker (FCC) cycle oil in their diesel pool. Refiners with large runs of highly naphthenic crudes could also be affected. This is typically much of California’s refining feedstock base.

Depending on the implementation of the California specifications, there will probably be some carry over to the remainder of the country. In the future, this might include some type of aromatics specification or a further increase in the minimum cetane index.

2.4.3 European and Worldwide Diesel Specifications

In much of western Europe, the sulfur specification is 0.30 weight% maximum. Sweden, Germany, and the Netherlands have reduced the sulfur specification to 0.20 weight%. The EU may move toward reducing the sulfur limit, although certain countries may again take the lead. Values that have been discussed range from 0.15 weight% down to the California, US, level of 0.05 weight% (500 ppm wt).

At present, there are no specific aromatics or cetane requirements for EU diesel. The large percentage of the diesel pool is from straight run stocks, so cetane tends to be inherently high. Sweden has tightened aromatics levels in what is called “city diesel” at 350 ppm. As more and more heavy oil conversion units are constructed, this picture may change and more universal limitations on aromatics and cetane may be expected.

The rest of the world still does not worry about diesel, with the exception of a few notable Asian countries, and Brazil, which recently has brought nearly all fuel sources under the 300 ppm limit.\(^\text{34}\)

2.5 Future Regulatory Trends

The dramatic rush by refiners worldwide to install regulatory controls in the mid 1990s was mercifully tempered by a minimum of new edicts about what specifications had to be met. The cost of meeting even US EPA Phase I requirements was too much for many US refiners, particularly those with a capacity under 50,000 BPD (barrels per day). Dozens of them were merged, closed or downgraded to oil storage terminals, simply from the excessive cost of making regulation gasoline in a competitive market. Refiners in California had a four-year lead on the rest of the country as the CARB standards basically matched US EPA Phase II. As the year 2000 approached, another round (though smaller than the first) of capital spending began in those remaining refineries that had not yet complied with the Phase II specifications.

Based on the fact that the last major legislation was written in 1991 for this regulatory activity, it would be reasonable to assume that within the next three to four years there will be further tightening of some of the standards in Tables 2, 3, 4, and 5. There is currently a rather heated debate on sulfur levels in gasoline and total aromatic content in all fuels. One can only expect the limits on both of these to go down. It is also likely that total reductions of all regulated components will be mandated based on some 1998–2000 timeframe emissions average criteria. There will also be a push to reduce nitrogen and more of the VOCs. One can examine the proposed Tier2 regulations being proposed\(^\text{35}\) that now extend to sports utility vehicles (SUVs), minivans, and light duty trucks.

The one exception to this trend to tighter specifications may be in the amount and types of oxygenate used. There has recently been a flurry of data and instances detailing contamination of groundwater supplies by MTBE, one of the more prevalent gasoline oxygenates. There are also some credible court challenges to the effectiveness of oxygenated compounds in reducing smog-forming components in air. It may well be a better idea to reduce such emissions by lowering sulfur content drastically, although this idea is also currently based more on circumstantial evidence rather than theoretical considerations.

3 CHEMICAL COMPONENTS OF PETROLEUM-DERIVED FUELS

Gasoline is a volatile mixture of liquid hydrocarbons suitable for use in spark-ignition internal combustion (IC) engines. Gasoline is formulated from the lighter ends of refinery runs and generally contains petroleum molecules having between four and 12 carbon atoms. This material is sometimes called light naphtha in the industry. Gasoline also typically contains small amounts of additives to prevent icing and corrosion and to improve engine performance. Refiners add high-octane oxygenates such as ethanol, methanol or MTBE or aromatics such as benzene, toluene or xylene to enhance octane. Kerosine and diesel stocks have slightly heavier components than gasoline averaging about 2–4 carbon numbers heavier than gasoline respectively on a size distribution scale. This material is often referred to as heavy naphtha.

3.1 Crude Oil Chemical Mixture Components\(^\text{37,20,21,36 – 39}\)

It is generally accepted that the origin of crude oil is from plant life up to 3 billion years ago, but predominantly from 100 to 600 million years ago. The molecular structure of the hydrocarbons and other compounds present in fossil fuels can be linked to the leaf waxes and other plant molecules of marine and terrestrial plants believed to exist during that era. There are various biogenic
marker chemicals such as isoprenoids from terpenes, porphyrins and aromatics from natural pigments, pristane and phytane from the hydrolysis of chlorophyll, and normal alkanes from waxes, whose size and shape cannot be explained by any known geological processes. The presence of optical activity and the carbon isotopic ratios also indicate a biological origin.

Hydrocarbons are any molecules that just contain hydrogen and carbon, both of which are fuel molecules that can be oxidized to form water ($\text{H}_2\text{O}$) or carbon dioxide ($\text{CO}_2$). If the combustion is not complete, carbon monoxide ($\text{CO}$) may also be formed.

The way that hydrogen and carbons bond determines which hydrocarbon family they belong to. If they only hold one common bond they are called “saturated hydrocarbons” because they cannot absorb additional hydrogen. If the carbons hold two common bonds they are called “unsaturated hydrocarbons” because they can be converted into “saturated hydrocarbons” by the addition of hydrogen to the double bond. Hydrogens are omitted from the following protocol for convenience, but if one remembers $\text{C}$ has between one and four bonds maximum, $\text{H}$ has one bond only, and $\text{O}$ has two bonds only, the full structures of most hydrocarbons can be quickly drawn.

Gasoline contains over 500 hydrocarbons that may have between 3 and 12 carbon atoms, and gasoline used to have a boiling range from 30–220°C at atmospheric pressure. The boiling range is narrowing as the initial boiling point (IBP) is increasing, and the FBP is decreasing—both changes are for environmental reasons. Detailed descriptions of structures can be found in any chemical or petroleum text that discusses gasolines.

Saturated hydrocarbons (paraffins, alkanes) tend to burn in air with a clean flame and form the stable, majority compositional segment of gasolines. They are subdivided into normal, iso and cyclic alkanes

- Normal alkanes have a continuous chain of carbon atoms ($\text{C}_n\text{H}_{2n+2}$), for example normal heptane (1) is

  \[
  \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} -
  \]

  (1)

  or $\text{C}_7\text{H}_{16}$.

- Iso alkanes have a branched chain of carbon atoms ($\text{C}_n\text{H}_{2n+2}$), for example isooctane (2) (or 2,2,4-trimethylpentane) is

  \[
  \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} -
  \]

  (2)

  or $\text{C}_8\text{H}_{18}$.

- Cyclic alkanes (naphthenes) have a circle of carbon atoms ($\text{C}_n\text{H}_{2n}$), for example cyclohexane (3) is

  \[
  \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} -
  \]

  (3)

  or $\text{C}_6\text{H}_{12}$.

Unsaturated hydrocarbons contain one or more double bonds between carbon atoms.

- Alkenes (olefins) have carbon–carbon double bonds ($\text{C}_n\text{H}_{2n}$), for example 2-methyl-2-butene is (4) or $\text{C}_5\text{H}_{10}$.

  \[
  \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} -
  \]

  (4)

These components are unstable and reactive with several chemicals, including themselves (polymerization) and are the principal “gum” formers in fuels. They also tend to burn in air with a smoky flame and typically have a foul smell. They are very rarely found to any extent in natural “straight run” cuts or in hydrotreated feedstocks but are a significant component of thermally cracked stocks such as from the FCC or Coker refinery units.

- Alkynes (acetylenes) have carbon–carbon triple bonds ($\text{C}_n\text{H}_{2n-2}$), for example acetylene (5) is

  \[
  \text{C} = \text{C}
  \]

  (5)

  or $\text{C}_2\text{H}_2$.

These are even more unstable, but are only naturally present in trace amounts, and only to a small extent in some poorly refined gasolines.

- Arenes (aromatic compounds) have one or more “benzene-type” rings with highly unsaturated but highly stable intercarbon bonding. For example benzene (6)

  \[
  \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} -
  \]

  (6)

  or $\text{C}_6\text{H}_6$ and toluene (7) or $\text{C}_7\text{H}_8$. 

  \[
  \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} - \text{C} -
  \]

  (7)
These are found to a small but significant extent in most petroleum stocks and are formed in most refinery cracking and reforming processes as well. Typical aromatics levels in gasolines used to be up to 40%, but are gradually being reduced to <20%. From a performance standpoint, however, the benzene, toluene and the xylenes give outstanding gasoline performance results and are difficult to replace in the gasoline supply chain. On the minus side, aromatics attack elastomers and generate smoke.

- Polynuclear aromatics (PNAs or PAHs) contain benzene rings joined together, the simplest of which is naphthalene (8)

![naphthalene](image)

These are high boiling, and are only present in small amounts in gasoline. The multi-ringed PNAs are highly toxic, and are not present in gasoline boiling range material but will be found in diesel stocks.

Oxygenates are mostly hydrocarbons which happen to contain oxygen, for example, ethanol C–C–O–H or C₂H₅OH and MTBE (tertiary butyl methyl ether) (9) or C₄H₉OCH₃. Their structure provides a reasonable anti-knock value, thus they are good substitutes for aromatics, and they may also reduce the smog-forming tendencies of the exhaust gases. They can be produced from fossil fuels such as methanol (MeOH), MTBE, tertiary amyl methyl ether (TAME), or from biomass such as ethanol (EtOH), ethyl tertiary butyl ether (ETBE)). Most oxygenates used in gasolines are either alcohols (Cₓ–O–H) or ethers (Cₓ–O–Cᵧ), and contain 1–6 carbon atoms. Oxygenates are added to gasolines to reduce the reactivity of emissions, but are only effective if the hydrocarbon fractions are carefully modified to utilize the octane and volatility properties of the oxygenates. If the hydrocarbon fraction is not correctly modified, oxygenates can increase undesirable smog-forming and toxic emissions.

![ethanol](image)

3.2 Typical Gasoline Mixture Components

During the 1990s, various compositional changes to gasolines for environmental and health reasons have resulted in fuels that do not follow historical rules, and the regulations mapped out for 2000–2010 also ensure that the composition will remain in a state of flux. The reformulated gasoline (RFG) specifications, especially the US EPA Jan 1998 Complex model, will introduce major reductions in the distillation range, as is now the case in California (CARB rules), as well as the various limits on composition and emissions.

It is not feasible to list all 500+ hydrocarbons in current gasolines, but those presented in Table 6 are representative of the various classes typically present in a straight run, a conventional (pre-Phase II) and a fully RFG. A traditional fuels cut composition from a normal conversion refinery would include the components given in Table 5. Newer oxygenated fuels (bottom of Table 6) reduce the aromatics and olefins, narrow the boiling range, and add oxygenates up to about 12–15% to provide the octane.

Some of the C₁₀+ components will be found in most gasolines, perhaps up to C₁₄, but volatility specifications require that very little of these be residual in the gasoline distillates. Gasoline components will more typically have C₆ to C₁₀ components, with an average of around 8.

There are some other properties of oxygenates that have to be considered when they are going to be used as fuels, particularly their ability to form very volatile azeotropes that cause the fuel’s vapor pressure to increase, the chemical nature of the emissions, and their tendency to separate into a separate water/oxygenate phase when water is present. The RFGs address these problems more successfully than the original oxygenated gasolines otherwise known as gasohols.

Some other fuel additives are typically formulated into the gasoline by the refiner. A typical gasoline may contain:

- Oil-soluble dye, initially added to leaded gasoline at about 10 ppm to prevent misuse as an industrial solvent,
- Antioxidants, typically phenylenediamines or hindered phenols, are added to prevent oxidation of unsaturated hydrocarbons,
- Metal deactivators, typically about 10 ppm of chelating agent such as N,N’-disalicylidene-1,2-propane-diamine is added to inhibit copper, which can rapidly catalyze oxidation of unsaturated hydrocarbons,
- Corrosion inhibitors, about 5 ppm of oil-soluble surfactants are added to prevent corrosion caused either by water condensing from cooling water-saturated gasoline, or from condensation from air onto the walls of almost empty gasoline tanks that drop below the dew point. If gasoline travels along a pipeline, it is possible that the pipeline owner will add additional corrosion inhibitor to the fuel,

</table>

MON, motor octane number.
<sup>a</sup> Compounds are too heavy for gasoline, but would be fine for kerosine and diesel.
<sup>b</sup> These olefins are not present in significant amounts in gasoline, but have some of the highest blending octanes and cetane values.

- Anti-icing additives, used mainly with carbureted cars, and usually either a surfactant, alcohol or glycol,
- Anti-wear additives, which are used to control wear in the upper cylinder and piston ring area that the gasoline contacts, and are usually very light hydrocarbon oils. Phosphorus additives can also be used for engines without exhaust catalyst systems.
- Deposit-modifying additives, usually surfactants. These include:
  1. Carburetor deposits – additives to prevent these were required when crankcase blow-by (PVC, polyvinyl chloride) and exhaust gas recirculation (EGR) controls were introduced. Some fuel components reacted with these gas streams to form deposits on the throat and throttle plate of carburetors.
  2. Fuel injector tips operate at about 100 °C, and deposits form in the annulus during hot soak, mainly from the oxidation and polymerization of the larger unsaturated hydrocarbons. The additives that prevent and unplug these tips are usually polybutene succinimides or polyether amines.
  3. Intake valve deposits (IVDs) caused major problems in the mid-1980s when some engines had reduced drivability when fully warmed, even though the amount of deposit was below previously acceptable limits. It is believed that the new fuels and engine designs were producing a more absorbent deposit that attracted some of the passing fuel vapor, causing lean hesitation. Intake valves operate about 300 °C, and, if the valve is kept wet, deposits tend not to form, thus intermittent injectors tend to promote deposits. Oil leaking through the valve guides can be either harmful or beneficial, depending on the type and quantity. Gasoline factors implicated in these deposits include unsaturates and alcohols. Additives to prevent these deposits contain a detergent and/or dispersant in a higher molecular weight solvent or light oil whose low volatility keeps the valve surface wetted.
  4. Combustion chamber deposits were targeted in the 1990s, as they are responsible for significant increases in emissions. Recent detergent-dispersant additives have the ability to function in both the liquid and vapor phases to remove existing carbon and prevent deposit formation.
  5. Octane enhancers are usually formulated blends of alkyl lead or manganese compounds in a solvent such as toluene, and added at the 100–1000-ppm levels. They have been replaced.
by hydrocarbons with higher octanes such as aromatics and olefins. These hydrocarbons are now being replaced by a mixture of saturated hydrocarbons and oxygenates.\textsuperscript{23,44}

### 3.3 Components in Heavier Fuels

Heavier petroleum fuels have similar components, only larger on average. Most of the components described above will be present to a smaller degree with significant amounts of higher boiling components, at least for those fuels derived from crude distillation. Many of the compounds with multiple aromatic or naphthenic rings have extended side chains as well. Most of the sulfur, nitrogen, and metals are concentrated in the diesel range components and are more than likely to be embedded inside an aromatic ring (RA). Thiobenzene and dithiobenzene are typical sulfur compounds. Pyridines and pyrroles are common nitrogen contaminant species. Metallic-centered porphyrins are the primary metals species for iron, nickel, and vanadium content.

Most of the same C\textsubscript{6}–C\textsubscript{10} components will be found in most heavier distillates. Kerosine will have significant amounts of up to C\textsubscript{14} (average about 10) and some diesel components may have a molecular carbon number as high as 18–20, although the average molecular number here is about 11.

### 4 PETROLEUM-DERIVED FUELS

#### 4.1 Spark-ignition Engines (Gasoline)

The critical factors in desirable performance of gasoline in a spark-ignition engine are volatility, antiknock quality, storage stability, component compatibility, and intake system deposit control. Gasolines are usually determined by government regulation, where properties and test methods are clearly defined. In the USA, several government and state bodies can specify gasoline properties. The US gasoline specifications and test methods are listed in several readily available publications, including the Society of Automotive Engineers (SAE) and the ASTM. These specifications, in fact, change from year to year so they are not listed with the year designation included. To do so would condemn this work to obsolescence very quickly. The latest editions, some having only minor changes in them from previous editions, can be obtained directly through ASTM or found in the nearest technical library.

ASTM D-4814 (Specification for Automotive Spark-ignition Engine Fuel) is the major standard for US automobile manufacturers to follow. Some of the considerations addressed therein are discussed in more detail below.

#### 4.1.1 Volatility Considerations

Spark-ignition engines need a volatile fuel for ease in starting, fast warm-up, and good drivability. In practical terms, this means a fuel that boils in the range 30–215 °C (85–420 °F). Too light a fuel leads to poor fuel economy (volatile volume loss), carburetor icing, and vapor lock in the fuel pump. Too heavy a fuel causes cold weather starting problems, poor drivability, engine deposits, and crankcase oil dilution.

Two primary standards for measuring gasoline volatility are distillation (ASTM D-86) and Reid vapor pressure (RVP) (ASTM D-4953). Distillation measures the boiling range of the hydrocarbons that make up the finished gasoline. RVP measures the pressure that the fuel exerts under conditions approximating those in an automobile carburetor. From these, a third standard vapor/liquid (V/L) ratio, can be calculated using the procedure in ASTM D-2533. The temperature where V/L = 20 indicates the tolerance of modern cars to vapor lock. The higher the temperature, the less chance of hot weather stalling. At low temperatures, other factors such as drivability must be considered. These factors are also controlled by ASTM D-86.

Gasoline specifications change seasonally in most areas of the world that have distinguishable seasonality. The reason for these variations is quite simple. In the cylinder only gaseous hydrocarbons burn, so if the air is cold, the fuel has to be very volatile. In summer, a volatile fuel can boil too readily and cause vapor lock, as well as producing high levels of evaporative emissions. The solution for automobile manufacturers was to adjust the volatility of the fuel according to altitude and ambient temperature. This volatility change has been automatically performed for decades by the oil companies without informing the public of the changes. It is one reason why storage of gasoline through the seasons is not a good idea.

Even as gasoline volatility is being reduced, modern engines, with their fuel injection and computerized management systems, can automatically compensate for some of the changes in ambient conditions such as altitude and air temperature, resulting in acceptable drivability using less volatile fuel.

ASTM D-4814 defines six different classes according to location and/or season. As gasoline is distilled, the temperatures at which various fractions are evaporated are calculated. Specifications define the temperatures at which various percentages of the fuel must evaporate. Distillation limits include maximum temperatures when 10% is evaporated (50–70 °C), 50% is evaporated (110–121 °C), 90% is evaporated (185–190 °C), and the
final boiling point (FBP) (225 °C). There is a minimum temperature for 50% evaporated (77 °C), and a maximum amount of residue (2%) after distillation. Vapor pressure limits for each class (54, 62, 69, 79, 93, 103 kPa) are also specified. The US EPA has issued a waiver that does not require gasoline/ethanol blends to meet the required specifications in certain areas of the United States. ASTM D-4814 also defines five classes for vapor lock protection, according to location and/or season. The limit is a maximum $V/L$ ratio of 20 at test temperatures of 41, 47, 51, 56 and 60 °C.

Volatility also affects combustion engine emissions. The higher boiling fractions of the gasoline have significant effects on the emission levels of undesirable hydrocarbons and aldehydes, and a reduction of 40 °C in the FBP will reduce the levels of benzene, butadiene, formaldehyde and acetaldehyde by 25%, and will reduce hydrocarbon emissions by 20%. (11)

4.1.2 Antiknock Quality

Under severe service conditions, spark-ignition engines are knock limited. High temperatures, high compression ratios, lean mixtures, and advanced spark settings lead to knock, which is the explosive combustion of the last part of the fuel/air mixture “end gas” drawn into the cylinder. A gasoline’s chemical composition determines its ability to resist knock.

The antiknock value(18,21,49) of a gasoline is measured in two standard laboratory engine tests. Both use the same type of single-cylinder variable-compression ratio engine attached to a dynamometer with the operating conditions changed only as needed. ASTM D-2699 describes the standard for determining RON and ASTM D-2700 pertaining to motor octane number (MON).

In both standard procedures, the compression ratio is adjusted to produce a measured level of knock with the test fuel, then the knock intensity with a primary reference fuel is blended to give the same, then rebleded for slightly better and finally for slightly worse antiknock performance. Because the reference fuels are known blends of isooctane (octane number of 100) and $n$-heptane (octane number of 0), the octane content of the fuel that exactly matches the knock intensity of the test fuel is its octane number. Of the two procedures, the MON test is more severe, correlating with high-speed high-temperature part-throttle service in an actual vehicle. The MON for most gasolines is lower than the less severe RON, which primarily correlates to a gasoline’s ability to resist run-on, after-run, or dieseling. The difference between the two ratings ($R - M$) is called the sensitivity.

Neither test exactly correlates with actual service in a car, where driving conditions vary continuously. Actual “road” octane number, otherwise known as antiknock index (AKI) is a better predictor of quality, and various procedures are available to measure this value, either on the road or the chassis dynamometer. Since no two cars rate gasolines exactly alike, RON cannot be used as a control test. As a compromise, the AKI has been developed. This is the arithmetic average of RON and MON, and is sometimes called simply the $(R + M)/2$ value. Where the law requires octane numbers to be posted on gasoline pumps, AKI is posted.

Gasoline specifications are written to reflect the octane number response (ONR) of the typical car population, but they also vary with location and season. Higher ambient temperatures and engine cylinder age increase ONR, while higher absolute humidity and elevation above sea level decrease it.

The most significant determinant of octane, of course, is the chemical structure of the hydrocarbons and their response to the addition of octane enhancing additives. Several other important properties of the fuel itself affect knock. Among them are:

- Front end volatility – Paraffins are the major component in gasoline, and the octane number decreases with increasing chain length or ring size, but increases with chain branching. Overall, the effect is a significant reduction in octane if front end volatility is lost, as can happen with improper or long-term storage. Fuel economy on short trips can be improved by using a more volatile fuel, at the risk of carburetor icing and increased evaporative emissions. The ASTM standards dealing with front-end volatility are D-86, D-2887, D-323, D-4953, D-5191, and D-2533.

- Final boiling point – Decreases in the FBP increase fuel octane. Aviation gasolines have much lower FBPs than automotive gasolines. Note that FBPs are being reduced because the higher boiling fractions are responsible for disproportionate quantities of pollutants and toxins. The ASTM standards dealing with back-end volatility are D-86, D-1160, and D-2887.

- Preignition tendency – Both knock and preignition can induce each other.

ASTM 4814 does not set limits for AKI, but changes in engine requirements according to season and location are discussed. Fuels with an AKI of 87, 89, 91 (unleaded), and 88 (leaded) are listed as typical for the USA. Analogous considerations for cetane number (CN) in diesel stocks are governed by ASTM D-613 and ASTM D-976.

4.1.3 Storage Stability

Gasoline deterioration in storage is caused mainly to oxidative processes. Oxidation leads to the formation
of gum, a varnish-like material that can build up in combustion chambers and intake systems, interfering with efficient engine running. In extreme cases, it can even cause ring sticking and engine seizure. To guard against this problem, refiners include antioxidants and metal deactivators, which reduce the catalytic effect of certain metals in promoting oxidation.

Specifications limit the amount of gum in fresh gasoline to 5 mg per 100 mL. These results do not correlate well with actual engine deposits caused by fuel vaporization and probably should be considered as a minimum. Laboratory oxidation tests control the extent to which oxygen will attack gasoline. Compliance with these limits usually ensures that gasolines will remain usable for up to 12 months. Any gasoline known to have been in storage longer than 6 months, however, should be retested before use. Because the oxidation rate doubles for every 10 °C temperature increase, storage conditions are important.

Storage time also increases the likelihood of a water–oxygenate phase separating from the hydrocarbon, so care should be taken with the “shelf life” of oxygen-containing fuels. Water tolerance via ASTM D-4814 sets the highest temperature that causes phase separation of oxygenated fuels. The limits vary according to location and month. For Alaska, north of latitude 62, it changes from −41 °C in Dec/Jan to 9 °C in July, but remains 10 °C all year in Hawaii.

Gums are usually the result of copper-catalyzed reactions of the unsaturated hydrocarbons, so antioxidants and metal deactivators are added. Existent gum is used to measure the gum in the fuel at the time tested, whereas the oxidation stability measures the time it takes for the gasoline to break down at 100 °C with 100 psi (690 kPa) of oxygen. A 240-min test period has been found to be sufficient for most storage and distribution systems.

Minimum oxidation stability tests ensure the fuel remains chemically stable, and does not form additional gums during periods in distribution systems, which can be up to 3–6 months. The sample is heated with oxygen inside a pressure vessel, and the delay until significant oxygen uptake is measured.

The ASTM standards dealing with storage stability in gasolines are D-381 and D-525.

4.1.4 Component Materials Compatibility

Minor amounts of nonhydrocarbon material found in, or added to, gasolines can have adverse effects on engine life and performance. Phosphorus and lead deactivate oxidation catalysts, and oxygenated materials such as alcohols and ethers can cause seal and fuel-line swelling as well as promoting engine rust.

Sulfur in the fuel creates corrosion and when combusted will form corrosive gases that attack the engine, exhaust and environment. Sulfur also can poison exhaust catalysts. The copper strip corrosion test and the sulfur specification are used to ensure fuel quality. The copper strip test measures active sulfur, whereas the sulfur content reports the total sulfur present.

ASTM D-4814 specifies lead content at the following levels for:

- Lead brands (where allowed) = 1.1 g Pb L⁻¹ maximum,
- Unleaded brands = 0.013 g Pb L⁻¹ maximum.

Most local jurisdictions allow for almost no lead, and trace analysis procedures may be needed to determine trace levels.

ASTM D-4814 only mentions copper strip corrosion as the ability to tarnish clean copper, indicating the presence of any corrosive sulfur compounds. Interpretation is left up to the refiner.

Maximum sulfur content via D4814 is specified at the following levels for:

- Lead brands (where allowed) = 0.15% mass (1500 ppm) maximum
- Unleaded brands = 0.10% mass (1000 ppm) maximum

Sulfur adversely affects exhaust catalysts and is typically emitted as polluting sulfur oxides. Typical US gasoline levels are 0.03% (30 ppm) by mass.

The ASTM standard dealing with materials compatibility for gasolines is D-130.

4.1.5 Intake System Deposit Control

The intake system includes either a carburetor, throttle body injector or port fuel injector, and intake valve stem, tulip, head, and intake manifold runners. Many gasolines contain unstable components that can lead to deposit formation in these high-temperature areas of the induction system. Gasolines for use as fuels in spark-ignition engines must be able to reduce or eliminate deposit formation in critical fuel-delivery system components. Since January 1 1995, the US EPA has mandated the use of detergent additives in gasoline in order to help reduce emissions and improve air quality.

During the 1980s significant problems with deposits accumulating on intake valve surfaces occurred as new fuel injections systems were introduced. These intake valve deposits (IVDs) were different from the injector deposits, in part because the valve can reach 300 °C. Engine design changes that prevent deposits usually ensure that the valve is flushed with liquid gasoline, and provide adequate valve rotation. Gasoline factors that cause deposits are the presence of alcohols or olefins.
Gasoline manufacturers now routinely use additives that prevent IVD and also maintain the cleanliness of injectors. These usually include a surfactant and light oil to maintain the wetting of important surfaces.

Figure 1 illustrates the fuel property/performance relationships of a modern gasoline.

4.1.6 Brands Differences/Additive Packages

The above specifications and standards are intended to ensure minimal quality standards are maintained, however as well as the fuel hydrocarbons, the manufacturers add their own special ingredients to provide additional benefits. A quality gasoline additive package would include:

- octane-enhancing additives (improve octane ratings)
- antioxidants (inhibit gum formation, improve stability)
- metal deactivators (inhibit gum formation, improve stability)
- deposit modifiers (reduce deposits, spark-plug fouling and preignition)
- surfactants (prevent icing, improve vaporization, inhibit deposits, reduce NOx emissions)
- freezing point depressants (prevent icing)
- corrosion inhibitors (prevent gasoline corroding storage tanks)
- dyes (product color for safety or regulatory purposes).

4.2 Aviation Gasoline

A special grade of gasoline is aviation gasoline, called avgas for short. It should not be confused with jet fuel which is essentially a kerosine-derived turbine fuel. Avgas is for smaller spark ignition aircraft engines. Most specifications for avgas cater to the safety factors at the expense of the economics. Distillations and volatility are more tightly controlled, as are contaminant levels. The octane requirements are higher to account for both the higher engine cylinder compression ratios and the devastation that could be caused by premature valve and lifter wear if cheap gasolines were routinely available to unsophisticated aircraft owners. Most other specifications follow those of automobile gasoline, including recent US EPA/CARB regulatory requirements. Significant exceptions are mentioned below.

4.2.1 Aviation Gasoline Antiknock Numbers

Aviation gasolines were all highly leaded and graded using two numbers, with common grades being 80/87, 100/130, and 115/145. The first number is the aviation rating (lean mixture rating), and the second number is the supercharge rating (rich mixture rating). In the 1970s a 100 LL grade (low lead = 0.53-mL TEL L\(^{-1}\) instead of 1.06-mL TEL L\(^{-1}\), TEL = tetra ethyl lead) was introduced to replace the 80/87 and 100/130. Soon after the introduction, there was a spate of plug fouling, and high cylinder head temperatures resulting in cracked cylinder heads. The old 80/87 grade was reintroduced on a limited scale.

The aviation rating is determined using the automotive motor octane test procedure, and then corrected to an aviation number (AN) using a table in the method – it is usually only 1 – 2 octane units different from the motor value up to 100, but varies significantly above that, e.g. 110 MON = 128 AN.

The second avgas number is the rich mixture method performance number (PN – they are not commonly called octane numbers when they are above 100), and is determined on a supercharged version of the constant fuel ratio (CFR) engine, which has a fixed compression ratio. The method determines the dependence of the highest permissible power (in terms of indicated mean effective pressure) on mixture strength and boost for a specific light knocking setting. The PN indicates the maximum knock-free power obtainable from a fuel compared to isooctane = 100. Thus, a PN = 150 indicates that an engine designed to utilize the fuel can obtain 150% of the knock-limited power of isooctane at the same mixture ratio. This is an arbitrary scale based on isooctane + varying amounts of TEL, derived from a survey of engines performed decades ago. Aviation gasoline PNs are rated using variations of mixture strength to obtain the maximum knock-limited power in a supercharged engine. This can be extended to provide mixture response curves which define the maximum boost (rich, about 11 : 1 stoichiometry) and minimum boost (weak, about 16 : 1 stoichiometry) before knock.\(^{45}\)
The 115/145 grade has been phased out in North America (though not everywhere else in the world), but the 100 LL is still in use and has more octane than any automotive gasoline. These specifications change much more slowly than automobile fuel specifications because the market is much smaller and safety for use in older aircraft is still considered an important criteria.

The basic ASTM standard dealing with avgas performance is D-910.

4.3 Compression–Ignition Engine (Diesel) Fuels

Compression–ignition (CI) engines run on mid-distillate fuels with boiling ranges higher than that of gasoline. The best diesel fuels are “straight-run” stocks, derived from simple distillation of crude oil, but many commercial fuels contain a proportion of catalytically cracked material.

The important properties of diesel fuels are volatility, heating value, ignition quality, 

4.3.1 Volatility

The volatility of a diesel fuel has little influence on its engine performance, except as it affects ignition tendencies. The distillation range of a diesel fuel does not allow much flexibility in this regard because of the interrelationship and interdependence with other specification factors. The controlling factor is the ASTM D-86 distillation 90% evaporated temperature.

Because diesel fuels are classified as nonflammable for freight purposes, minimum flashpoint restrictions are imposed. The ASTM standards dealing with diesel flashpoint are D-93 and D-95.

4.3.2 Heating Value

Fleet operators, rail and shipping companies are concerned about fuel economy. They aim to use the fuel with the greatest heating value, provided that other specification requirements are met. The factors that influence heating value are density and mid-boiling point (bp).

4.3.3 Ignition Quality

This factor influences ease of starting, duration of white smoking after start-up, drivability before warm-up, and intensity of diesel knock at idle. Studies have correlated ignition quality with all regulated emissions. As ignition delay is reduced, the combustion process starts earlier and emissions (primarily CO and hydrocarbons) are reduced.

4.3.4 Cetane Number

Ignition delay is measured by the CN test (ASTM D-613), which uses a single-cylinder, variable compression ratio engine analogous to the octave number engine. The factor measured is ignition delay (rather than knock) at a fixed compression ratio, and it is compared with that of standard reference fuels consisting of blends of n-cetane and heptamethylnonane. The cetane content of the blend that matches the ignition delay of the test fuel is the test fuel’s CN. It is diesel’s analog to gasoline. Few laboratories are equipped with cetane engines, so a number of correlations between CN and physical properties have been developed as substitute methods. Best known is the ASTM D-976 calculated cetane index, which uses the density and mid-bp of the fuel.

Diesel engines vary more widely in their cetane requirements than do automobiles in their octane requirements. In general, the slower an engine’s operating speed, the lower the CN of the fuel it can use. Large marine engines can tolerate fuels with CNs as low as 20, while some manufacturers of high-speed passenger car diesel engines specify 55 CN fuel. Railroads purchase fuel to a 37 or 38 CN minimum specification, but most truck manufacturers call for a 40 or 45 minimum. CN can be increased by using cetane improvers. These additives, usually organic nitrates, boost CN by 2 to 7 numbers, depending on the dosage and type of base stock used. These additives directly contribute to NO emissions, however, and have come under scrutiny from various regulatory agencies.

4.3.5 Viscosity

Viscosity influences the spray pattern when the fuel is injected into the cylinder. Low-speed marine engines can use higher viscosity fuels than high-speed road transport engines, and still run without excessive smoking. Minimum viscosity limits are imposed to prevent the fuel from causing wear in the fuel injection pump.

4.3.6 Low-temperature Flow

Unlike gasolines, which have freezing points well below even the most severe winter ambient temperatures, diesel fuels have pour points and cloud points well within the range of temperatures at which they might be used. This presents no problem on ships or even in railroad applications where heated storage can be arranged. However, for on- and off-highway use, precautions must be taken to tailor the low-temperature properties of the fuel to the weather.

Seasonal blending to control cloud point (the temperature at which wax separates from the fuel) is the refiner’s assurance against field problems. ASTM D-97 is the procedure used to determine a fuel’s cloud and pour points. In the winter, there is an increasing tendency to use flow
improvers, polymeric additives that modify the wax structure as it builds up during cooling. These additives keep wax crystals small, so they can pass through the fine pores of fuel filters en route to the injector pump. With suitable base stocks, flow improvers can keep an engine running at temperatures as much as 10°C below the fuel’s cloud point.

In addition, pour point depressants are sometimes used in diesel fuel to ensure that it can be dispensed at low temperatures. Tests such as the cold filter plugging point (CFPP), IP 309, are used to assess the potential of a diesel fuel to have cold weather field problems.

Other ASTM standards dealing with cold environment performance, are D-2500 and D-4539.

4.3.7 Storage Stability

In storage, diesel fuels are attacked by atmospheric oxygen, which can cause deposition of varnish, and for marine fuels containing residual components, asphaltic material. Antioxidants and dispersants are added to prevent such problems, while copper metal deactivators reduce the catalytic effects of screens and other parts. In the presence of water, bacterial action can cause a build-up of slime in the storage system, leading to filter plugging. Biocides are added to inhibit bacterial growth. In cold weather areas, there is the risk of static electric charges building up during high-rate dispensing of distillate fuels. Refiners include antistatic additives in diesel blends to prevent explosions.

The ASTM standards dealing with storage stability in diesel cuts are D-381 and D-5304.

4.3.8 Component Materials Compatibility

Diesel fuels are injected into the engine through precision pumps and fine injector nozzles. Dirt and water contamination must be avoided to protect these critical components. Specifications include tight limits on water and sediment, but some fuel marketers also install final filters at the nozzles of service station pumps to protect against dirt picked up in the distribution system.

Depending on the crude source, diesel fuels contain various amounts of sulfur compounds, which yield corrosive sulfur oxides on combustion. These can cause high rates of engine wear and rapid depletion of engine oil additives. Engine manufacturers often relate oil change intervals to the fuel sulfur content.

Deposit buildup in engines is influenced by fuel quality. Fuels that leave a heavy carbon residue and contain excessive amounts of high-bp materials are prone to cause engine deposits. Therefore, limits are placed on carbon residue and ASTM D-86 90% evaporated temperature.

Again, as for gasoline, the ASTM standard dealing with materials compatibility is D-130.

4.3.9 Sulfur Content

Sulfur content is the first diesel fuel property to be widely controlled by legislation aimed at limiting exhaust emissions. Sulfur is present in all crude oils and refined products. During combustion, sulfur compounds burn to form acidic by-products, SO₂ and SO₃, which form sulfates in the exhaust gas stream. Sulfates are part of a diesel engine’s particulate emissions; therefore, controlling fuel sulfur level reduces the level of sulfate pollutants.

4.3.10 Water Content

All diesel fuels contain small amounts of water. The amount that a fuel can hold is controlled by hydrocarbon type and distribution, and bulk temperature. As temperature decreases, the amount of water dissolved in the fuel will also decrease and may lead to a water layer forming on the bottom of the storage vessel. This layer should be minimized by draining the tank regularly to prevent bacterial contamination and the pumping of water into the fuel distribution system. Excessive water in a fuel system can cause corrosion, filter plugging and icing (in the winter).

A tabular summary of diesel fuel performance/property relationships is presented in Table 7.

4.4 Aviation Turbine/Jet/Marine Fuels

The important properties of kerosine-derived turbine fuels are volatility, heating value, low-temperature cloud point, storage stability, component compatibility, and sulfur content. There is no overall defining specification for a generic turbine fuel because of the wide variety of engine types and requirements that the fuel must meet. There are standards, however, for individual turbine fuel types mostly defined by the type and service of the turbine involved. The most important standards are set by military requirements since jet fuels are the biggest users of this fuel stock. In spite of this, there are far fewer performance requirements than for spark or compression ignition engines. The current ASTM standard for turbine fuels performance is D-1655.

There are also some ISO standards for performance and scores of military specifications (nearly one for each country with an airforce), some of them conflicting in minor areas with the other specifications. It would seem that, unlike normal gasoline purchase customers, the military block in the world both sets the refining specifications and buys the product that they have specified and subsequently use. Quantity purchases allow for this customer perquisite. Fortunately, most of these specifications agree in important areas. If they did not, there would be major problems with some jet fuels, of which the only indication might be a crashed plane. Thus, jet fuel misspecification problems are somewhat self-limiting.

The overall performance standard for this fuel is D-1655.

4.4.1 Volatility

The volatility of a turbine fuel has little influence on its engine performance, except as it affects exhaust smoking tendencies and fuel efficiency. The distillation range of jet fuels is tightly defined by military jet engine specifications and have been so for years. As with gasoline, a controlling factor is the ASTM D-86 distillation 90% evaporated temperature.

Because turbine fuels are often handled in large quantities by numerous commercial and military installations, minimum flash point restrictions are imposed. ASTM D-56 is the applicable standard here. This also makes it easier for refiners to store jet cuts than for them to store the more volatile gasoline blend stocks and products.

A consideration for static electricity buildup (non-ionic, nonelectrolyte fluid flowing through a metal conducting pipe tends to do this for gasoline, kerosine, and diesel cuts) should be mentioned. There is no such standard for gasoline or avgas, although the problem can exist with them as well. The diesel flash point and flammability characteristics generally (not always, but typically so) rule out severe static susceptibility. The typical military quarter-master loves to have specifications for nearly everything; therefore the static ignition on jet fuels is maintained. ASTM D-4856 is a rough composite of several historical military specifications combined with some practical materials engineering and grounding practices.

4.4.2 Heating Value

The same considerations apply here as for the diesel fuel heating value commentary.

4.4.3 Low-temperature Flow

Unlike gasolines, which have freezing points well below even the most severe winter ambient temperatures, kerosines would normally have cloud points well within the range of temperatures at which they might be used. This presents no problem on ships or even in railroad applications where heated storage can be arranged. Wax formation in high-altitude aircraft is extremely hazardous to flow of the fuel to the aircraft engine. Since ambient temperatures in such an environment may be $-20\,^\circ\mathrm{F}$ ($-29\,^\circ\mathrm{C}$) or less, jet fuels have a large number of guidelines for what they may contain. Error in specification formulation for jet fuels is always on the side of safety.

4.4.4 Storage Stability

In storage, jet/turbine fuels like gasoline are also attacked by atmospheric oxygen, which can cause deposition of varnish and gums, but since these fuels typically are used in high volumes, long-term storage problems are not of as much concern. Usually military specifications prescribe refining procedures that minimize the amount of oxygen-sensitive contaminants in the fuel as delivered. Water is always a problem, however, especially in humid climates. In the presence of water, bacterial action can cause a buildup of slime in the storage system, leading to filter plugging. Biocides are added to inhibit bacterial growth. In cold weather areas, there is the risk of static electric charges building up during high-rate dispensing of distillate fuels. Refiners include antistatic additives in jet fuel blends to prevent explosions.

4.4.5 Component Materials Compatibility

Kerosine fuels are injected into the engine through pumps and injector nozzles. Dirt and water contamination must be avoided to protect these components, but the greater need is to protect the turbine engines and their high-speed moving parts. Most jet specifications include tight limits on water and sediment, but some fuel marketers also install final filters at the nozzles of aircraft service

4.4.6 Benzene and Toluene

The governing performance standard here is ASTM D-3601.

5 SOURCES AND FORMULATION OF TRANSPORT FUELS

5.1 Refinery Configuration

5.1.1 Introduction

Because the greatest abundance of transportation fuels in the world is derived from petroleum-based hydrocarbons, it makes sense to examine the workings of a petroleum refinery briefly. As mentioned before, naturally occurring petroleum has in its mix light naphtha, heavy naphtha, and light gas oil used respectively in gasoline (automobile and aviation), kerosine, jet/turbine fuels and diesel products. In the earliest days of the industry, these products were simply distilled from the feed oil. It has been said that the modern IC engine was basically built as a means to take advantage of the cheap and abundant “white gas” by-products of the refining of petroleum into lamp oil, lube stock and wax products more in demand at the end of the 19th century. Now, of course, the automobile and its demands virtually determine the market for petroleum and its products worldwide.

Today’s sophisticated transport machinery has more exacting specifications than can be typically met by using direct distilled, or as commonly known, “straight-run” fractions. In order to meet these requirements, refineries are designed to make a number of motor fuel components and streams which vary greatly in octane, volatility and other drivability parameters.

Refineries not only differ in size (BPD of crude processed), they comprise different processes and operations (configurations). The configuration of a refinery depends primarily upon the type of crude(s) available as feedstock and upon the product slate requirement. In general, the products which dictate refinery design are relatively few in number, and the basic refinery processes are based on the high-volume products such as gasoline, jet fuel and diesel fuel. Storage and waste disposal are expensive. It is necessary to sell or use all of the items produced from crude oil even if some, like heavy fuel oil, must be sold at a price less than the crude oil cost. Careful economic balances are required to determine whether certain crude fractions should be sold as is (straight-run) or further processed to increase their value.

5.1.2 Types of Refineries

The simplest and earliest configuration is the skimming (topping) refinery, a schematic of which is shown in Figure 2. Here the major processing step is crude oil distillation, the object being to remove the lighter fractions from the residuum. When only one distillation column is used, it is operated at atmospheric pressure. Typical products will be gases, light naphtha, heavy naphtha, light gas oil, heavy gas oil and a 675°F residuum. A second distillation column operating under vacuum may be added to gain more, and heavier, gas oil. This in turn produces less, but a heavier (975°F), residuum.

The liquid sidestream products are further stabilized in individual strippers before leaving as “straight run” naphtha, and so on. Contaminants are not removed in straight-run products and are present in proportion to their distribution in the whole crude. Also the quality

Figure 2 Topping plant scheme.
Figure 3 Modern conversion refinery.

(Octane, pour point, contaminant levels, etc.) of these straight-run oils is usually at a minimum level.

A more complex configuration results when hydrotreating processes are added to remove contaminants from the straight-run oils (hydroskimming refinery). Figure 3 shows a simplified process block flow diagram of this kind of plant. Olefins and aromatics are also saturated in hydrotreating. To supply the hydrogen consumed in these processes a catalytic reforming operation is often included which itself greatly increases the octane pool potential of the refinery (at the expense of adding a lot of benzene and aromatics to the mix). If reforming does not produce sufficient hydrogen, a hydrogen manufacturing unit must be added, too.

Hydrotreating increases the quality of the liquid products primarily from an environmental cleanliness standpoint by removing the sulfur, nitrogen, and some metals impurities. In some instances, benzenes and other aromatics can also be removed by hydrotreating, though this option is fairly expensive.

Catalytic reforming increases the quality of the naphtha by raising the octane number rating of the clear unleaded gasoline fraction.

When the market for gas oil products is smaller than their yield, they are cracked to lower boiling range sales products such as liquefied petroleum gas (LPG), gasoline and diesel fuel. This is done by catalytic cracking (FCC unit) or hydrocracking units. Because the product slates of these two processes are different, market requirements must be considered in choosing which one to use. In most large refineries, both types of cracking will be used.

Hydrocracking consumes a large quantity of hydrogen (1500 to 2500 standard cubic feet per barrel) which is much greater than that produced by catalytic reforming. A hydrogen manufacturing plant is included in these refineries to supply this excess. The need for a separate hydrogen plant as well as the high operating-pressure requirements, make hydrocracking an expensive operation. This is made up for by the significantly higher quality products which are formed.

If the residuum (heavy fuel oil) produced exceeds the market demands, some type of residuum treatment process must be incorporated. In a conversion refinery a visbreaker or delayed coking or fluid coking is used to crack the residuum to naphtha, distillate and gas oil product. When the coke market is small and the
refinery can use low British Thermal Unit (Btu) fuel gas, flexicoking might be used. Alternatively, a residuum hydrocracker may be used to upgrade the entire stream.

The liquid products from a coking process generally are not very stable. They contain olefins and active aromatics and have high sulfur and nitrogen contents. These liquids are usually hydrotreated to improve their quality.

Figure 3 is a simple block flow diagram of a modern conversion refinery. A comparison of Figures 2 and 3 graphically illustrates some of the increased complexity of modern refinery processing. This particular example has three processes for handling the vacuum residuum: solvent deasphalting, delayed coking and fluid/flexicoking. Many refineries, particularly in cold climates, do find it economical to produce a significant amount of heavy fuel oil in addition to fuel-directed naphtha and coke by-products.

Another option for residuum processing, if the main crude has the proper makeup, is lubricants production. Not all crudes have an abundance of good lube stock components. The main feedstock for lube oil products is usually heavy vacuum gas oil. Lube oil can also be made from hydrotreating/hydrocracking products so there can be a variety of configurations to include this capability. In the refinery of Figure 3 several additional steps would be added. The lube oil feedstock (vacuum gas oil, deasphalted oil, etc.) would be sent to a solvent extraction unit. Here aromatics and other undesirable components are removed to produce a stable oxidation-resistant lube oil product. The lube oil is further treated by solvent dewaxing to lower the pour point. The dewaxed oil is then clay treated to decolorize it to produce the final product.

When a refinery has thermal cracking (visbreaking or coking) or catalytic cracking, significant quantities of light olefins (ethylene, propylene, butadiene, etc.) are produced. Some refineries include processes such as ethylene/propylene separation and butadiene separation in addition to aromatics (benzene, toluene, xylenes) separation. These materials are then sold as petrochemical feedstocks.

A critical process for making reformulated fuels is the alkylation unit. This unit takes isoparaffins and combines them with olefins to produce longer-chain branched naphtha molecules. By using only C₃ to C₅ olefins with isobutane, high octane, low olefin, low RVP, no-aromatics gasoline can be made. While the alkylation product is an extremely valuable commodity, the capital and operating costs of alkylation units are quite high and are catalyzed by either sulfuric or hydrofluoric acid which present refiners with some safety and environmental concerns of their own.

Table 9 shows a textual explanation of the source and distributions of typical refinery streams.

5.2 Fuels Blending

Modern gasolines have such a variety of specifications to be met in each blend run, as many as 30 including those for both performance and environmental criteria. Few if any of the process unit naphtha streams in the refinery (a dozen at most) could singly meet them all. This represents a mathematical imbalance that can be rectified only by using a fairly sophisticated blend procedure to minimize both deviations from specification and economic giveaway. Some of the streams are more expensive to make than others and if one particular blend were to take too much of a more desirable feedstock, say alkylate (low RVP, high octane, no aromatics or olefins), the refinery would be left with no choice but to use the other stocks for its subsequent product demand. This, in turn, gives a greater risk of making off-specification material or will force the refinery to cut production capacity in other units in order to restore blend stock ratios. Neither option should be used very often in today’s competitive market. A downgrade of premium fuel to regular grade, or from CARB spec to US EPA Phase I specification may cost as much as $4.00 per barrel of product which is a $280,000 loss for a 70,000 BBL blend run.

The specifications themselves may also vary in type and approach to blending implementation. The normal drivability and regulatory specifications mentioned elsewhere in this article are diverse indeed. Most are expressed as either minima or maxima, some being one or the other, others with widely varying bounds on both sides of a tolerance range. A few such specifications, octane rating being the most prominent, may have tolerance limits so narrow as to be essentially a fixed value. In this case the minimum specification would be determined by commercial or contractual needs and the maximum might be from the standpoint of refinery “giveaway” economics.

Figure 4 shows a basic analyzer-control schematic for fuels blending.

Commercial methods for blending motor fuels may be one of two kinds, batch tank blending or the more modern in-line blending. Small sequential batch-to-receiving tank blending (the traditional way) is normally time-consuming and involves trial-and-error testing until a given batch meets specification, making allowances for testing errors. Modern refineries have generally adopted some modification of direct in-line blending or massive blend tank (50,000 BBL at a time) batching with multiple simultaneous stock feeds. These methods have some outstanding advantages. They are continuous (or mostly so with giant size batches) rather than batch mode, thus saving time. They provide a much closer control in meeting critical specifications and require less tankage.

The multiple feedstock protocol generally prescribes

</tbody>
</table>

that the blend header specification must quickly become “on-spec” within a certain percentage of the blend having traveled down to the receiving tank and the total blend run, plus the residual “heel” in the blend tank must blend together and still meet specifications. True “in-line” blending directly to customer carrier (pipeline, railcar, tanker) is even more stringent procedurally. The product must be “on-spec” almost immediately and the total blend must meet specs – there obviously is no room at all for reblends in this case.

In-line blending became a practical reality with the advent of sophisticated, automated equipment and instruments, along with distributed (computer) control systems. With this method, the first step is to produce in segregated tankage the required amounts of several appropriate blend components which, according to the blender’s calculations, will result in meeting the target blend specifications when the components are blended in the proper proportions. Close control of certain specifications of these components as they are produced, particularly RVP and octane number, is achieved by continuous monitoring, using suitable automated equipment. The final step is to pump these components at controlled rates into a common line that discharges into a vessel which may be a tank, pipeline, barge, or a tanker. This operation can be activated and controlled by a suitable advanced computer control system.

Figure 5 displays the approach to final blend value of RVP and RON for an 87.5 RON regular grade of unleaded fuel. Notice the approach to the target of RVP as opposed to that of the octane. Before RFG, the giveaway strategy would have been reversed.
5.3 Advanced Control and Monitoring of Gasoline Blending

5.3.1 Introduction

The following description is a typical procedure that might be followed in the course of setting up and running a gasoline blend in a semi-batch fashion in typical runs of 20,000 to 150,000 barrels sizes depending upon the size and complexity of the refinery.

The key to success is getting all the right information to flow around the system. Blend recipes from the refinery planning group must be received in proper and timely fashion by the blend operators, who must then set up the actual plant flow paths to accomplish the blend.

Historically, this function was a simple matter of verifying the availability of stocks and setting the blend ratio by hand or setting up a sample slave-ratio controller to maintain the recipe. Trim control of rates during the run was a relatively simple matter. With the advent of several additional constraints upon the final product specification and availability of almost no new stocks for the planners, the problem of making both customers and regulators happy with the final product took on a new dimension.

With several reductions in available degrees of freedom, the mathematical solution to this problem became a matter of a QP (quadratic programming) optimization problem, with the objective function being a residual sum of squares error on quality targets and optimal recipe targets. Without the use of high-quality analysis feedback and a multivariable controller (MVC), it would be nearly impossible for a refinery to blend Phase II fuels and stay in business for long.

5.3.2 Blend Run Set-up for Execution

The first thing that must be transmitted before a blend is configured is the blend summary, which contains approved blend entries downloaded to the blending system from a blend planning engineer. These recipes are based on optimized recipes run through a multiperiod optimizer (typically linear program (LP) with recursion or successive linear program iteration, called SLP) to handle the nonlinearities of predicting stock octane and assay blending. Most commercial systems have what might be
called a blend summary administration screen. The blend summary screen might display such minimum information as blend identification, finished product to be made (type, name, etc.), receiving tank, target volume, plus start and stop times.

Underneath the blend summary screen one should expect a blend entry screen which holds all the information needed functionally to define a blend. This would include one or more subdisplays for blend administration information plus the month/season for quality specifications to be met for this product, target volumes of feeds and product to be blended, receiving tank identifier and initial volume (heel) for finished product tank, percent of blend volume by which the finished product tank must meet specifications.

A more specific type of control screen is for blend recipe control. Information here would cover such items as components or additives to be used in a blend, primary source tank for feed component/additives, secondary component/additive source tanks to use in place of primary tank (if, perhaps, this tank runs low and approaches its minimum safe heel), component recipe percentages defined by the blend engineer, off-line optimizer results that are placed here when an off-line optimizer is run and its results are accepted, minimum and maximum component recipe percents, and other information needed by the blender operator.

Yet another screen typically separates feedstock control from final product control. Such a blend quality control screen allows the blend operator to specify or control the following: the finished product quality, blended product quality values as projected by the blend engineer to start the blend, minimum and maximum product specifications, blend move limits, constraints the quality should have a limit on; maximum (high) constraints, minimum (low) constraints, or should not limit at all (or let the optimizer use these limits), and finally blend header quality values, from the starting recipe to the final recipe projected by the off-line optimizer. Most blender systems also have text entry blocks that allow the operator to make comments to describe any special conditions of this blend, alarm summary statistics, automatic management report generation and routing, and so on.

Once the blend entry is defined and set up by the operator, equipment for flow control of the blend must be selected. The operator chooses the appropriate blend entry (from several that are being planned or that may be available for execution) for run preparation. A flow path must be chosen for each component tank. This path defines the pump(s) and meter(s)/flow controllers(s) to be used for this blend component. A default path is typically suggested by the system. This default path or another path may be used. The path flow limits are calculated for the pump/meter combination of the chosen loop. If the component flow rate required to achieve the blend rate is outside of the equipment flow limits, a message indicates this condition. The operator can choose a different loop or go ahead with this choice on the understanding that the necessary component flow cannot be reached.

A typical blend equipment selection screen displays the following: tank movement status (current flows into and out of the stock tanks), component/additive or finished product tank to be used in the blend, material in the tank, primary and secondary pump and flow meters used for component, product transfer for this particular loop, minimum and maximum limiting pump or meter flow rates, component/additive or finished product flow rate required for specified blend entry.

The basic blender control systems will stop here. The more sophisticated ones will include not only multivariable control functions but economic optimization control as well. This feature can be divided into two phases of operation, off-line and on-line optimization.

5.3.3 Off-line Recipe Blend Optimization

After equipment has been selected for the blend entry, an off-line optimizer can be used to check the feasibility of the intended blend with actual current system values. Current tank qualities are used in the off-line optimization. The off-line optimizer is fundamentally the same as the on-line optimizer in that it uses the current rundown rates, tank inventories, and batch transfers in checking stock availability. This helps to find potential problems with the blend before the blender is actually started. If the product specification qualities cannot be met using the specified component recipe and constraints in the blend entry, the optimizer will give an infeasible result (and hopefully flags it to the operator as such!). This feature provides an important check on the validity of the refinery planning function where the original blend recipe originated. In a typical refinery, the planning group may not have access to all of, or even the same, information that the blend operator has.

The goal of an off-line optimizer is to find a recipe which primarily meets quality specifications for the product at or before the end of the blend, then secondarily reduces quality giveaway. The objective function is a minimization of recipe deviations and quality giveaway. Constraints for this optimization include final product quality constraints, recipe limits, path flow limits, and tank working volume limits.

An infeasible result means that the product quality specifications cannot be met with the components in the current recipe and the current path constraints. The constraints could be made less binding or the recipe could be changed. In any case, the limiting constraints will have
to be modified and the optimizer rerun until a feasible result is achieved.

If the results are feasible, the optimized recipe can be accepted into the blend entry, replacing the previous initial recipe used for the optimization. Off-line optimizers will typically show the blend engineer the following information: type of constraint encountered from beginning of blend to on-spec percentage of total blend, optimized component recipe from on-spec percentage of total blend to end of blend, optimizer result – infeasible or feasible, optimized quality value at both the blend header and receiving tank when on-spec percentage is reached and when end of blend is achieved, path flow limits and infeasibilities, and stock tank conditions at end of blend. Finally, there needs to be a means of accepting the results (basically a yes or no answer.) A feasible result only should be accepted for download into the blender distributed control system (DCS).

5.3.4 Blend Run Initialization, Launch and Monitoring

When the results of the off-line optimizer are satisfactory, the blend entry information can be passed to the header quality control function and downloaded to the DCS to initialize the blender. The recipes, quality targets, and most blend entry information are passed on to the DCS. Recipe and quality targets are passed to the header multivariable controller (MVC) quality controller. The blend entry is then executed from the DCS. After the blend is started and operating near full flow rate, on-line optimization and header quality control can be activated.

Figure 6 shows a schematic of an MVC based CARB blender package.

During the blend, header qualities are monitored by intermittent on-line analyzers, calculated, and manually entered data. The analyzer values are available through the DCS. For every on-line analyzer, a good/bad status is needed to indicate whether the value is useful for control. For each analyzer, a status is required to indicate when a new result is available.

A well-designed blend launch and monitoring screen displays the standard blend identifier information plus header and predicted tank qualities in real time, analyzer status (good/bad) and results along with ongoing predictions of header qualities, real-time tank movement data, updated laboratory results, and alarm messages for problems and constraints encountered during the run. For US EPA Phase II or CARB specification blending, a multivariable advanced controller is essentially a necessity. The operators should always be able to see the status of

![Figure 6 Multivariable blender control (PLC = programmable logic controller).](image-url)
the MVC unit and the metrics by which its control can be judged.

Figure 7 shows a typical control strategy that typically might be used on a CARB blend recipe. Only three control variables (CVs) are targeted and only a total of seven are available with the stocks available to the blender in this case. Controlling the T10 and the RVP simultaneously, in fact, often poses control problems. If this happens, one or the other criteria must be relaxed somewhat. In typical MVC systems, a two sided control range is an indication that a quality has a regulatory (usually maximum) constraint and a set of economic criteria (if not exactly constraints) or performance quality constraints which are usually the determinants of the lower control constraints. Such conflicting goals are the reason that MVC is essential in making CARB or Phase II gasolines.

Figure 8 shows the essential monitoring function that a quality controller must be able to perform. The final tank or target pipeline specification must continually be examined for predicted to measured accuracy and corrective action taken if discrepancies occur, including shutdown reoptimization of the recipe and restart of the blend process.

5.3.5 On-line Blend Optimization\(^{(59–62)}\)

As the blend run proceeds, the controller varies the signals sent to the individual component flow loop controllers based on the multitude of information received from flow meters, pump motor power meters, analyzers, temperature and pressure indicators and perhaps a parallel predictive or “virtual” model of the blend properties as well. The MVC tries basically to minimize the deviation of all flow rates from the specified setpoints. All controller output moves that it makes come from the multivariate nature of the blend problem with competing specifications and quality needs that require constant give and take in order to minimize the deviation from the target of any one quality in the final blend.

Most MVC installations control a combination of predicted qualities modified by regularly updated analyzer values during the course of the run. For whatever reasons, the predicted and measured qualities will diverge to some extent. Occasionally this divergence is significant. In such cases, with the MVC package and being constantly mindful of constraints and competing quality requirements, the blend is still quite feasible but may no longer be as economical as possible. An on-line optimizer provides the blend operator with a chance to redefine the remainder of a blend recipe based on a set of economic and operating criteria.

The result of an on-line optimizer is a new set of setpoint targets. Generally, on-line optimizers will run every 2–10 min, constantly reexamining the “optimal blend” problem based upon what has already been passed through the blend header and what is still left in the stock tanks, all the while heeding the same quality specifications and process constraints that govern the MVC. When the new “optimal” and current setpoints differ to some significant amount, the on-line optimizer will flag the condition and suggest that the blend operator makes a move. Usually the new setpoints end up being the ideal resting values (IRVs) for the MVC as it wrestles with the multiple specification problem it must satisfy. Making these IRVs the new setpoints will usually make the MVCs job easier and the control of the blend becomes quite stable in operation. Every once in a while, a well-designed on-line optimizer will recognize money-making opportunities such as the opportunity to blend more butane or high RVP straight run naphtha into a blend that is otherwise heading towards a serious RVP “giveaway” situation.
6 FUELS ANALYSIS FOR REGULATORY REQUIREMENTS

6.1 Introduction
The technology available for the chemical and physical characterization of petroleum and chemical feeds and products has improved steadily. Better detectors and better electronics have resulted in higher sensitivity and speed of analysis for many of the more well-established techniques. At the same time, new scientific concepts and the availability of low-cost minicomputers have resulted in the creation of new techniques that provide novel information. The integration of the information from these new, and often extremely expensive, instruments results in a remarkably detailed knowledge of the composition of various process and product streams, particularly when the various separation processes are appropriately combined with the other instrumentation. The following sections provide a brief summary of the more commonly used techniques available today, together with a number of basic references that provide a more detailed discussion of both the scientific principles and areas of application for each system.

6.2 Analytical Procedures – Component Separation Methods

Petroleum streams and chemical feedstocks are usually quite complex mixtures and the analysis of these systems can frequently be simplified through some form of prior separation. The separation techniques commonly employed are distillation, to narrow the boiling range, and chromatography, which provides both boiling range and compound-type separations. Much of the recent progress in obtaining more detailed compositional data on petroleum and chemical streams can be attributed to the wide use of chromatography. Such separation techniques are also used to isolate pure compounds or compound types needed as calibration standards for the instrumental methods described later.

6.2.1 Distillation
Distillation tests are generally performed on products destined to be used under conditions involving conversion to the vapor state. Thus, the distillation characteristics of all fuels are important quality considerations. Since solvent quality depends on the rate of evaporation, distillation characteristics are also important for this type of product. In the case of heavier products such as lubricating oils, distillation is carried out under reduced pressure to avoid cracking. Here distillation characteristics are useful in predicting oil consumption in automotive crankcases in certain types of automotive service.

Distillations are reported in one or more of the following terms:
1. IBP
2. distillation temperatures for increments of volume overhead
3. percent evaporated at specific temperatures
4. EP or maximum temperature
5. dry point
6. recovery or loss
7. residue.

Five standard laboratory procedures for distillation of petroleum-based fuels have been standardized. Three are run at atmospheric pressure and one at reduced pressure. Four of the atmospheric methods, D-86, D-216, D-285, and D-1078 are of a type that results in a very modest degree of fractionation effected by a minimal reflux of the distillate in the neck of the flask. The method at reduced pressure, D-1160, is designed to attain fractionation equivalent to about one theoretical plate. A gas chromatographic (GC) method, D-2887, is now available. It is roughly equivalent to D-86 but requires some conversion of the raw data. D-216 is little used now, as the naphtha fractions from current gas plant liquids recovery almost always goes through a stabilization process designed to fit certain D86 cut requirements.

Table 10 shows the standardized distillation procedures for the various types of petroleum products.

Briefly, the distillation procedure consists of heating a sample in a flask fitted with a thermometer, and then causing the vaporized portions to pass through a tube condenser which extends through an ice–water bath and into a glass cylinder graduated in milliliters. Readings show the amount of sample evaporated at a given temperature. A diagram of a basic laboratory apparatus for D86 analysis is shown in Figure 9.

When the first drop falls from the end of the condenser, the reading of the distillation thermometer is recorded as the IBP. The heating of the sample continues at a uniform rate and the volume of distillate collected in the cylinder is observed and recorded to the nearest 0.5 mL, as the thermometer reaches each multiple of 10°C, or the temperature is recorded when the distillate level reaches each 10-mL mark on the graduate. The EP or FBP is the highest

temperature observed, which is usually reached just as the flask bottom has become dry. Appropriate corrections to the results are made for evaporation loss and barometric pressure. In manual mode, the ASTM distillation procedures require a substantial amount from the laboratory technician. Fortunately, several vendors have made modifications to the apparatus of Figure 9 which automate the heating and volume–temperature accounting process. It should also be noted that the initial and FBPs are somewhat subjective in nature and are, therefore, the least accurate points of the entire assay curve.

All distillation procedures are designed to give results which throw some light on the suitability of the various products for their particular use. All these procedures cannot be described in detail or the significance of their results discussed in this text. However, the quality of motor gasolines as judged from distillation data is presented as being typical of the use of distillation characteristics. Of these procedures, D86 is probably the leading standard. Several methods of measuring volatility via alternative methods, primarily gas chromatography (GC), have come into wide use but they all have the common denominator of requiring calibration standards set by the D86 standard.

### 6.2.2 Chromatography

As either a separation or as an analytical technique, chromatography\(^{(52,60)}\) may be conveniently divided into two categories: GC, and liquid chromatography (LC).

It has been generally found that LC complements GC as a separation tool in the laboratory. LC is ideally suited to samples that are nonvolatile or are sensitive to heat. It generally separates on the basis of compound type. In contrast, GC separates partly on polarity and partly on the basis of volatility, and therefore molecular weight has an influence on the separation. If one employs a special packing in LC, such as a cross-linked polymer with a controlled pore size, separation according to molecular size can be achieved. This is called gel permeation chromatography (GPC). This technique is especially valuable for the determination of molecular weight distribution in polymers and resins.

Here are some additional standards that may be applicable in chromatographic analysis of regulated fuel components.

- ASTM-F1374 – Ionic/organic Extractables of Internal Surfaces-LC/GC/FTIR (Fourier transform infrared) for Gas Distribution System
- ASTM-E1642 – General Techniques of Gas Chromatography Infrared (GC/IR) Analysis, Standard Practice
- ASTM D-3710 – Boiling Range Distribution of Gasoline and Gasoline Fractions by Gas Chromatography, Standard Practice
- Also ASTM D-3710, D-2427, ASTM F-1374, D3606, and D4815 have pertinent sections that apply to chromatographic methods.

#### 6.2.2.1 Gas Chromatography

Since its commercial inception in the 1950s, GC\(^{(69)}\) has had astronomical growth in analytical laboratories. The ease of use and versatility of the equipment has allowed gas chromatographs to be used for process as well as laboratory bench instruments.

Basically, GC is a simple technique. A typical GC schematic is shown in Figure 10. A sample is injected onto a column through which a carrier gas is flowing. A typical sample size for a liquid is of the order of a microliter; for a gas, a few milliliters. Liquid samples are vaporized in a heated injection block located ahead of the column. Some solid samples can be handled by using a special solid inlet system. The column is the heart of any chromatographic separation and may take any one of a number of forms. It is either a stainless-steel tube, about 3-mm inner diameter, packed with an inert solid coated uniformly with a liquid of low volatility, or a capillary tube, about 0.3-mm inner diameter, whose interior wall is coated with the liquid. As the sample is carried along by the gas, separation occurs by differential partitioning between the gas and the liquid coating. A large choice of liquid substrates is available, so
that the selectivity of the column may be matched to the mixture to be separated. The length of the column may vary from several centimeters for packed columns up to a hundred meters for the capillary. The column is housed in a temperature-controlled oven, the temperature of which can be increased according to a preset program. This had the advantages of either shortening the analysis time or improving the separation, or both.

As sample components are eluted from the column, they are sensed by a detector, the signals from which are recorded. The intensity of the signal is a quantitative representation of the amount of each component. There are a variety of detectors to ensure proper detection of the compounds of interest from the standard hydrocarbon analysis, such as sulfur, nitrogen, halogen and organometallics. Some are general purpose detectors, e.g. thermal conductivity or flame ionization, the latter having essentially equal sensitivity to all hydrocarbons. Others are sensitive to specific elements or compound types. For example, microcoulometers have been used to detect sulfur- and nitrogen-containing compounds in gas oils and other petroleum fractions, while electron capture detectors are highly sensitive to halogens and aromatics. Gas chromatographs have been successfully coupled to the more exotic mass spectrophotometers, Fourier transform infrared (FTIR) and atomic emission spectrum (AE) detectors.

GC is used to characterize a wide variety of hydrocarbon samples. Identification and measurement of the 500 or more components in gasoline are made routinely by GC. For analyses such as these, identification of the components eluting from the column is made by comparing their retention times to the retention times of reference materials, using carefully reproduced chromatographic conditions (column, temperature, flow rate, etc.).

This speciation process is necessarily a slow procedure which usually requires several hours. By contrast, GC distillation data are obtained in much less time, usually one hour or less. If the chromatograph is part of an automatic data handling system, a continuous curve of temperature vs percent overhead can be printed out by a computer-controlled plotter.

Column selection has been expanded to include capillary columns, meaning that the need for knowledge in selecting the right column is important. Capillary columns give the chromatographer the capability successfully to measure compounds that were difficult to measure in the packed column days.

While this new equipment has been developed to enable users to make measurements more accurately and faster at lower detection levels, a whole new set of problems arise with sample and data handling techniques used with new equipment. The trade-off of this new high-tech capability is the need for highly exacting techniques for handling the samples. Since smaller and smaller quantities of material are needed for the analysis, the significance of small levels of contamination becomes magnified. The quantities of material being injected are a
fraction of what they were during the packed column days. Sample sizes were large enough to overcome cross-contamination from a poorly flushed injection valve. Today, one must be concerned about micro levels of cross-contamination, sample cleanliness and sample volumes.

The smaller sample quantities compound the effect of contamination in several ways. From the use of syringes to the use of sampling valves for injection, attention to the sample preparation has become paramount to the analysis, second only to the method/application being used to measure the components of interest. The systems used to introduce the samples have also undergone a radical transition. Many of the new systems are capable of detecting very low quantities of components in a very short time.

Analytical expectations also are different now. In 1980 or even by 1990, refiners were concerned about percent and parts per million levels of detection. Now they are faced with lower levels of detection, parts per million, parts per billion and even parts per trillion levels, with coincident delivery of results in real time.\(^{(69)}\)

6.2.2.2 Liquid Chromatography

LC has undergone a radical change. The analysis time has been shortened from hours to minutes and the efficiency of the columns has been increased to several thousand theoretical plates per foot. This has been made possible primarily because of the advent of new high-pressure pumps and small-diameter packing materials for columns.

The schematic shown in Figure 10 is equally applicable to LC and GC by replacing the gas elutriant with a liquid one. Between 1–20µL of a solution of the sample are injected onto a packed column through which a liquid is flowing under pressure. The pressure, which may be up to 40 MPa is needed to achieve adequate flow rates; up to 5 cm³ min⁻¹. The injection block and column are usually maintained at ambient temperature. The column may be packed with a solid such as silica gel, forming a “liquid–solid” chromatograph. This solid may be modified by adding a liquid coating, which may or may not be chemically bonded to the surface, resulting in a “liquid–liquid” chromatograph. Separation is achieved by differential partitioning between the moving liquid phase and the stationary solid or liquid phase. The flowing liquid plays an active role in the separation process, and its choice, together with that of the stationary phase, determines the selectivity of the column. To shorten analysis time and to improve resolution, the composition of the moving phase can be changed as the analysis progresses. This is called solvent programming and is analogous to temperature programming in GC.

As the components are eluted from the column, they are sensed by a detector, two types of which are used most commonly. One type, the refractometer, senses a change in the refractive index of the solution and is a general detector, i.e. it will sense any component eluting from the column as long as its refractive index differs from that of the solvent. A second type is a visible range or UV spectrophotometer, and is specific for materials that absorb in a preselected part of the spectrum.

Several LC methods are now used – medium pressure, high-performance liquid chromatography (HPLC), and thin layer methods being the more popular test procedures. They mainly are used on diesel stocks, often to determine aromatics. The calibration techniques to do this are fairly rigorous, and, to date, few standards apply for regulatory purposes.

6.3 Electromagnetic Field Spectroscopy\(^{(20,63,67,68,70,71)}\)

6.3.1 General

Electromagnetic field (EMF) spectroscopy is the science of measuring the absorption and emission by atoms and molecules of electromagnetic radiation and of interpreting the results in terms of the composition and structure of such materials. As described in the following sections, spectroscopy can be subdivided into a number of separate fields of endeavor, each related to the various subsections into which the electromagnetic spectrum is commonly divided. The different fields yield different information on the structure and composition of both organic and inorganic materials and between them they are capable of providing a great deal of analytical information of importance to the following and understanding of petroleum and chemical processes. Quantitative spectrophotometric analyses can be accomplished by using Beer’s law (Equation 1), where

\[
I = \frac{I_0}{T} \quad \text{or} \quad A = abc = \log\frac{I_0}{I}
\]

where \(I\) is the intensity of the radiation of a given frequency falling upon the sample, \(I_0\) is the intensity transmitted through the thickness \(b\) (in cm) of the sample. The zero subscript refers to the transmission of the standard solution at a known calibration value, \(c\) is the concentration of the sample (g⁻¹) in the thickness \(b\), and \(a\) is the absorptivity or absorbance of the sample, a constant for a material at a given frequency.

The absorbance is more simply related to the concentration and absorptivity than is \(I\) and so is therefore commonly employed for quantitative analysis. The ratio \(I/I_0\) is the percentage of radiation transmitted and is commonly known as transmittance, \(T\).

6.3.2 Infrared Spectroscopy

Infrared (IR) absorption spectroscopy\(^{(72,73)}\) covers generally that part of the electromagnetic spectrum between
about 10 000 and 50 Hz (1–200µm), though in practice the bulk of the work is somewhere between 4000 and 200 Hz (2.5–50µm) in what is referred to as the near-infrared (NIR). The energy of the radiation in this region of the spectrum corresponds to the energy range characteristic of molecular vibrations, and such radiant energy can be absorbed by resonance interaction. A plot of the amount of energy absorbed vs. the frequency of that energy results in a complex spectrum that is unique to the absorbing molecule. Large catalogs of spectra of pure compounds exist and so it is relatively straightforward to identify an unknown material by comparing its IR spectrum with that of known reference compounds. It is also found that similar chemical structures absorb in a characteristic and relatively small range within the overall spectrum; for example, all carbonyl groups, >C··O, absorb in the region 1650–1800 Hz. Therefore, the presence or absence of such functional groups as ketones, alcohols, esters, carbonates, nitriles, and so on, can readily be determined in pure compounds or complex mixtures, both organic and inorganic. Such mixtures may be solids, liquids, or gases.

IR spectroscopy is widely used for the identification of unknown compounds or materials and for the components in many complex mixtures. It can be used to determine the structure of organic and inorganic compounds and to determine both the structure and conformation of polymers. It can also be used quantitatively for the analysis of, for instance, additives in lube oils, copolymer compositions and aromaticity.

### 6.3.2.1 Fourier Transform Infrared Analysis (FTIR)

FTIR technology, one of many flavors of IR spectroscopy, is perhaps the most widely used methodology aside from GC for on-line analysis of hydrocarbons. An FTIR unit typically operates by continuously extracting a sample that is filtered, pressure-regulated, and temperature-controlled in the sample system cabinet. All three of these operations are critical to accuracy. The sampling system must also be responsible for introducing reference samples, wash solvents and sample cell purging.

The analysis is performed by measuring the absorption caused by the compounds as the IR beam passes through the sample cell. The absorption in any one unique frequency is proportional to the concentration of the components in the sample, but with a mixed sample, several different frequency responses may be received additively or may cancel each other via wave physics. The system computer receives the detector signal and simultaneously records an interferogram from the hundreds of spectral patterns it gets. At the end of the test, the computer recalculates the original spectra using fast Fourier transform (FFT) mathematics, a decades old signal processing technology that has become popular with the advent of personal computers and benchtop workstations. The computer then reports the revised component type analysis (from its reference sample database) and component concentrations in standard engineering or scientific units.

and reformer naphthas with corresponding data in Tables 11 and 12.

Here are some additional standards that may be applicable for use of IR and UV spectroscopy analysis of regulated fuel components:

- ASTM-E204 – Identification of Material by Infrared Absorption Spectroscopy, Using the ASTM Coded Ba
- ASTM-F1374 – Ionic/Organic Extractables of Internal Surfaces-GC/FTIR for Gas Distribution System
6.3.3 Ultraviolet/Visible Spectroscopy

UV/visible absorption spectroscopy\(^{(71)}\) covers that region of the spectrum between 195 and 1000 nm. Absorption of energy in this region by molecules results in transitions between electronic states and, as with IR spectroscopy, such a spectrum can be used to provide information on the structure and composition of a sample. The most valuable analytical information from a petroleum and chemical processing point of view is obtained on molecules containing highly conjugated systems, particularly aromatic hydrocarbons and conjugated olefins, because such molecules have characteristic spectra and very high absorptivities.

UV/visible spectroscopy is the most powerful method for identifying and measuring trace (ppm–ppb) quantities of PNA hydrocarbons in hydrocarbon systems, particularly in combination with GC and other separation techniques.

6.3.3.1 Fluorescent Indicator Adsorption

Fluorescent indicator adsorption (FIA) technology is the most widely used methodology aside from GC for on-line analysis of hydrocarbons with multiple carbon–carbon bonds such as olefins and aromatics. FIA has been an ASTM standard for over 40 years, first appearing as such in 1954, so it is well known and established. It is inexpensive to implement in spite of the fact that it is still a laboratory based manual method. FIA determines the relative amounts of saturates, olefins and aromatics well enough to often substitute for some of the more expensive PIANO testing equipment mentioned in this section. Even so, there has been some controversy about its use for regulatory olefins emissions analysis.

A FIA unit operation is based on the separation of hydrocarbon components according to their adsorption affinities on activated silica gel. A sample is introduced onto the top of a bed of silica gel and packed in a glass column of small, uniform diameter. Isopropyl alcohol is added to desorb the sample and force it down the column. The components with the least affinity for silica gel are the saturates, which move to the front of a traveling band of sample. Those with progressively higher affinities (olefins and aromatics) lag behind.

Fluorescent dyes, visible under UV light mark the zonal boundaries of the saturates, olefins, and aromatics. The amount of each hydrocarbon type, in volume %, is calculated from the length of the zone. Because the fluorescing bands have a measurable length, which can be significant relative to the zone length of a particular hydrocarbon component, differences in “reading” the position of the boundary add a source of potential error to the determination.

The presence of significant C\(_4\) and C\(_5\) volatiles in gasoline leads to low-olefin readings compared to other PIANO-type analyses on the same sample composition. A note warning of this possibility appears in the ASTM D-1319 standard which also states that samples containing more than 5% C\(_4\)S or 10% C\(_4\)S + C\(_5\)S should be depentanized prior to analysis. This extra distillation step does not help the reproducibility of the method.

The author also has had trouble with FIA results for high-olefin stocks such as catalytic gasoline which will routinely contain 25–50% olefins. Any values above 30–35% give FIA readings that are suspect at best.

Here are some additional standards that may be applicable for use of UV spectrophotometry analysis of regulated fuel components:

- ASTM D-1017 – Benzene and Toluene in 250 F and Lighter Petroleum Products by Ultraviolet Spectrophotometry.

6.3.4 Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) is a form of radiofrequency spectrometry which uses the weak magnetic properties of atomic nuclei that possess nuclear magnetic moments. The most notable nuclei for petroleum characterization are H and C, the latter of which is only 1% abundant in nature. In the presence of a strong applied magnetic field the nuclear magnetic dipoles have certain preferred orientations, or energy levels, the energy separation of which is directly proportional to the total magnetic field sensed by the nuclei. The total magnetic field is the sum of the large applied field and very small molecular magnetic fields which are sensitive to the details of the environment of each nucleus. At a fixed applied magnetic field, chemically distinct nuclei will absorb at slightly different radiofrequencies. These small differences in absorption frequency are referred to as chemical shifts. Interaction between nearby magnetically nonequivalent nuclei may result in multiple absorption peaks for the particular nucleus affected. The number of peaks observed and the spacing between them varies in a predictable manner and is referred to as the spin–spin splitting pattern.
Both the chemical shift and the spin–spin splitting pattern are useful for determining molecular structures. A third important feature of NMR spectra is that the relative areas of the absorption signals of the various nuclei are proportional to the number of nuclei giving rise to the NMR signals. Thus, quantitative measurements are made by integrating the area under the signals, or peaks, which are due to different groups.

Proton (H) NMR is rapid and nondestructive. It has long been a useful ally of GC and mass spectrometry for characterization of volatile petroleum fractions. Determination of olefin type and the degree of branching in saturated side chains are typical applications. Proton NMR has the additional advantage of being applicable to high-boiling fractions and residues.

Developments in NMR techniques have made C NMR a practical reality. Carbon-13 NMR is difficult because the magnetic isotope (C13) is only 1% of the naturally occurring isotopes of carbon. The great advantage of C13 NMR is its much greater chemical shift range (100 times that of proton NMR). Moreover, C13 NMR probes the carbon skeleton directly, rather than inferring this information via the protons in the molecule. The result is that C13 NMR is many times more powerful than H NMR for characterization of complex hydrocarbons. Carbon-13 NMR provides a direct determination of aromaticity (% aromatic carbon), degree of aromatic substitution, and has the potential to provide a detailed analysis of side chain structure (average chain length, branching, etc.). Exploration of the full potential of C13 NMR for petroleum characterization is an active area of research.

Some ASTM standards for specific component analysis are:

- D-2622, D-4294 for sulfur in petroleum stocks,
- D-4059 for lead in petroleum stocks,
- D-3701, D-4808 for hydrogen content in petroleum stocks.

### 6.3.5 Emission Spectroscopy

When the atoms of a material are subjected to an electric arc, spark, or hot flame, electrons in the atoms are excited to energy levels higher than the ground state. When these electrons lose their excitation energy, light is emitted in the UV and visible region of the spectra. The electronic transitions involved are discrete so that a set of spectral lines is produced which is characteristic of the emitting atom. Furthermore, the intensity of the spectral lines is proportional to the number of emitting atoms. Thus, the emission spectrum can be used both to identify which elements are present in a material and to measure the concentration of the various elements. Quantitative work does, however, require that suitable standards be available for comparison.

The essential components of an emission spectrograph include (1) a radiation source, (2) an optical analyzer, and (3) a detector.

The radiation source includes the sample to be analyzed and a means of excitation such as the electric arc or spark. With these forms of excitation an electrical current is passed between two electrodes either as a continuous arc or as a spark. If the sample is a metal, the sample itself can serve as one or both electrodes. For other types of sample carbon electrodes are generally used to contain the sample during excitation. The actual design of the electrode will depend on the form of the sample and the elements of primary concern. Both liquid and solid samples can be analyzed.

The optical analyzer serves two functions in the spectrographic system. It provides a sharp image of the radiation emitted from the excited source, and it separates the radiation into its component wavelengths. The focusing required to produce a sharp image of the source is accomplished with lenses or focusing mirrors. The spatial separation of the light as a function of wavelength is accomplished with a diffraction grating; a flat piece of glass, metal or plastic on which are ruled a large number of parallel grooves (6000–10 000 grooves per centimeter).

The detection of the dispersed radiation is generally accomplished with a photographic plate or a photoelectric detector. Photographic plates are generally used for qualitative work because a wide range of wavelengths can be recorded simultaneously. The analysis of an unknown spectrum is accomplished by comparing it to reference spectra of known elements. Quantitative analysis is generally performed on instruments which utilize photoelectric detection. In practice, instruments designed for quantitative analysis often have a number of photoelectric detectors (up to 48) which can be set for different wavelengths. It is thus possible to perform simultaneous multielement determinations with this type of equipment. In principle, every element in the periodic table can be analyzed by emission spectroscopy, but it is routinely useful with approximately 70 elements. Qualitative analysis data can be obtained on as little as 0.1 mg of a solid sample, and under favorable conditions concentrations down to a few parts per billion can be determined.

The technique is used extensively in such problems as the analysis of wear metals in lube oils, qualitative analysis of corrosion products, and the determination of catalyst impurities.

#### 6.3.5.1 Flame Ionization Detection

This is probably the most common emissions spectroscopic method used for hydrocarbon analysis. Most commercial implementations have excellent sensitivity and stability at parts per
million levels of detection, even in harsh process conditions. Since sample flow, flame and temperatures are constantly monitored, maintenance and error detection are greatly simplified. FIDs (flame ionization detections) are easily automated and pair well with elution-type analyzers such as a GC.

The analyzer operates by burning the sample (vaporized) in a hydrogen-based flame. The hydrocarbons present are ionized in the flame and have the ability to conduct electricity through the flame to a collection grid surrounding the flame. By applying a high-voltage charge to the flame tip, the hydrocarbons in the sample can be measured by monitoring the current reaching the collection grid. This technique is not only sensitive to general hydrocarbons but those with easily oxidized heteroatoms as well – sulfur, chlorine, and so on.

Here are some more standards that may be applicable in emission spectroscopic analysis of regulated fuel components:

- ASTM D-3605 – Trace Metals in Gas Turbine Fuels by Atomic Absorption and Flame Emission Spectroscopy

6.3.6 Atomic Absorption Spectroscopy

Atomic absorption spectroscopy, a technique related to emission spectroscopy, is used to measure the concentration of a wide range of metallic elements. In this technique, a sample is vaporized in a flame or on a carbon rod and the vapor is irradiated by a lamp which has a cathode made from the element being sought. Electrons in the ground state atoms produced by the flame absorb the resonance lines emitted by the lamp and are thus excited to a higher energy level. The amount of energy absorbed, measured using a photodetector, is related to the concentration of the element present in the sample. The usual operating range of the method is from less than 1 ppm to about 100 ppm.

Some particular applications to the industry include the determination of metals in crude and refined products, in the additives in lube oils, and in aqueous systems such as effluent waters.

Here are some more standards that may be applicable in atomic absorption spectroscopic analysis of regulated fuel components:

- ASTM-E885 – Analyses of Metals in Refuse-derived Fuel by Atomic Absorption Spectroscopy, Standard T
- ASTM-E924 – Quality Assurance of Laboratories Using Molecular Spectroscopy, Standard Guideline for
- ASTM D-4053 – Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy, Standard Test Method for
- ASTM D-3831 – Manganese in Gasoline by Atomic Absorption Spectrometry, Standard Test Method for
- ASTM-E131 – Molecular Spectroscopy, Standard Terminology Relating to

6.3.7 X-ray Analysis Techniques

X-rays are produced when fast-moving electrons, or other X-rays, interact with the atoms of a target material. The primary mechanism of the interaction involves displacement of an inner electron from an atom, followed by the “falling” of an outer electron into the resultant hole. An X-ray photon, whose energy is the difference between the energies of the inner and outer electrons, is produced. Electron energies differ from element to element, and so the emitted X-ray energy is characteristic of the atom from which it was generated. Since atoms contain many different electrons, a number of characteristic X-ray energies are associated with each element.

In addition to the characteristic X-ray spectrum of a material, a continuous spectrum is also produced. This is due to a loss of energy when an electron interacts with the strong electric field of an atomic nucleus. This energy loss appears as an X-ray photon. The energies of the X-rays produced by this mechanism are independent of the nature of the atoms being bombarded and appear as a band of X-rays of continuously varying energy.

X-rays are characterized by either their wavelength or their energy. Equation (2) relates the two quantities

\[ \text{change in energy} = \frac{hc}{\text{wavelength}} \]  

(2)

where \( h \) is Planck's constant and \( c \) is the speed of light.

The X-ray region of the electromagnetic spectrum covers a range from 0.02 Å to slightly over 100 Å (1 Å = 10^{-10} m). The use of X-rays with wavelengths larger than about 2.5 Å, however, requires special vacuum techniques to minimize photon losses caused by air absorption.
There are three different X-ray techniques used for analysis: diffraction, fluorescence (emission) and absorption. X-ray diffraction is used most in analysis of solid crystalline structures and will not be discussed further in this article.

6.3.7.1 X-ray Fluorescence

The characteristic radiation produced when a material is bombarded with X-rays or electrons can be used to identify which elements are present in the material and to measure the concentrations of the various elements. The identification of unknown elements in a sample is based on comparing the wavelengths or energies of the observed X-rays to the known values for the elements in the periodic table. The concentrations of the elements are determined by measuring the intensities of the characteristic X-rays and comparing these to the measured X-ray intensities in suitable standards. In practice, the technique is generally limited to elements with a greater atomic number than 11 (sodium). It is often called chemiluminescence.

X-ray fluorescence instrumentation may be classified as either wavelength dispersive or energy dispersive. Wavelength dispersive systems employ a single crystal which separates the various characteristic X-rays by diffraction according to Bragg’s law. The resulting diffracted X-rays are detected by a scintillation counter or a flow proportional counter. Because X-rays with different wavelengths are spatially separated, measurements in a multielement system are conducted sequentially. Energy dispersive systems utilize a solid-state detector which is capable of both counting the number of incident X-rays and sorting them according to energy. Since information on all elements in a sample is received simultaneously, a device like a computer is needed to store the information. In general, multielement analyses are conducted more rapidly with an energy dispersive system. Furthermore, for most energies, the resolution of a wavelength dispersive system is superior to that of an energy dispersive system.

Elemental analysis on both liquid and solid samples can be carried out by X-ray fluorescence. The optimum concentration range for analysis is generally down to about 1 mg g⁻¹. In many cases, however, concentrations as low as a few micrograms per gram can be determined without great difficulty. The major experimental requirement for elemental analysis by X-ray fluorescence is that standards which match the composition of the samples of interest be available for instrument calibration. A variety of sample preparation and measurement techniques have been developed to meet this requirement. The most recent developments in this area include the use of various mathematical techniques to correct measured intensities for changes in the sample matrix. The successful application of these techniques greatly minimizes the amount of sample preparation required.

Some of the major applications of X-ray fluorescence include the determination of metals in catalysts, the determination of trace metals in cracking feedstocks, the determination of lead and sulfur in petroleum fuels, and the determination of additive components in lubricants.

A derivative method involves the bombardment of material with neutrons and measurement of the X-ray spectra emitted. This method is used in some on-line flow measurements.

6.3.7.2 X-ray Absorption

The third X-ray technique used for analysis is X-ray absorption. All materials absorb X-rays, some more than others. The relationship which governs the absorption process is the Beer–Lambert law, Equation (3)

\[ I = I_0e^{\mu t} \]  

where \( t \) is the thickness of the absorber, \( p \) is the density of the absorber, \( u \) is its mass absorption coefficient and \( I \) and \( I_0 \) are the transmitted and incident X-ray intensities. \( u \) is a function of both the elemental composition of the absorber and X-ray wavelength or wavelengths used. At fixed wavelength, the mass absorption coefficient can be expressed in terms of the elemental composition of the absorber in the following manner, Equation (4)

\[ u = \sum u_iW_i \]

where \( u_i \) is the mass absorption coefficient of the \( i \)th element in the sample and \( W_i \) is its corresponding weight fraction.

From this it is clear that a measurement of the transmittance \( (I/I_0) \) is not sufficient to determine the concentration of all \( I \) elements in a sample. Good results can be obtained, however, in specific applications where only one component of a sample is varying, where all other components are comparatively weak absorbers, and where any change in density of the sample is due to the variation in the one component. In such cases the transmittance of the sample at fixed thickness can be calibrated in terms of the weight concentration of the varying component. This technique is well suited, for example, to the continuous monitoring of TEL metals or sulfur in gasoline or in a hydrocarbon matrix.

Here are some additional standards that may be applicable in the use of X-ray analysis of regulated fuel components:

- ASTM D-2599 – Lead in Gasoline by X-ray Spectrometry, Standard Test Method for
- ASTM D-3229 – Low Levels of Lead in Gasoline by Wavelength Dispersive X-ray Spectrometry, Standard Test Method
6.4 Mass Spectrometry

The mass spectrometer is a most useful analytical tool in petroleum laboratories. This is due to the availability of good commercial instruments and to the capability of mass spectrometry to analyze complex mixtures rapidly and accurately.

The basic principles of mass spectrometry are simple. A sample is allowed to evaporate into a reservoir at about 47 × 10⁻⁴ kPa. It then enters the mass tube through a small leak or orifice, the pressure in the mass tube being maintained at between 1.3 × 10⁻⁴ kPa (no sample) and 1.3 × 10⁻⁶ kPa (with sample). A small proportion (about 0.2%) of the atoms are ionized by electrons emitted from a hot tungsten filament. This “electron gun” creates 70-V energy electrons. The ions “crack” into charged fragments and these fragments are accelerated through the mass tube in a magnetic field. The ion paths are altered by the magnetic field in direct relation to their mass, the path of a low mass ion being bent more than that of a high mass ion. By varying either the magnetic field or the accelerating voltage in a continuous manner, one mass at a time passes through the exit slit of the mass tube to the collector plate. After amplification, a mass spectrum of mass numbers vs currents is recorded. The fragmentation pattern of a compound serves to identify the components present in the sample.

Mass spectrometry is applied to the analysis of gases, liquids, and solids. This technique requires about a microliter of liquid sample and a few milliliters of gas, at atmospheric pressure, for analysis. Quantitative determination of complex mixtures can be achieved by proper selection of analytical points (mass/charge) for the compounds present and setting up and solving the sets of simultaneous equations obtained.

One application of mass spectrometry in the petroleum field is for the analysis of gaseous mixtures. Mixtures containing 20 or more components can readily be analyzed. Examples include the products from catalytic crackers and hydroformers, which are analyzed for C₁ through C₅ hydrocarbons, fixed gases, and hydrogen. Although a complete isomer breakdown is not made, sufficient information is obtained to satisfy most requirements. This has been a particularly useful measurement in the case of hydroformate make-gases where the sample may contain as much as 95% hydrogen. It is possible to determine some 19 other components in the remaining 5% of the sample.

Mass spectrometry is also used for the analysis of petroleum liquids. Light (C₅ – 121 °C) naphthas can be analyzed for individual paraffins, naphthenes, and aromatics. Samples boiling in the gasoline range can be analyzed for total paraffins, total noncondensed naphthenes, condensed naphthenes (2, 3, 4, etc. rings) and for C₆, C₇, C₈, C₉, C₁₀ benzenes and naphthalenes. Heating oils and lube oils can be analyzed for both aromatics and saturates. The aromatics determined are 2, 3, 4, etc. ring-type as well as the same ring-type thiophenes. The saturates determined are the total paraffins, noncondensed naphthenes, and condensed naphthenes (2, 3, 4, etc. rings). Many of these samples, of course, may be solid at room temperature. Other solid samples analyzable by mass spectrometry include refined waxes, which are analyzed for normal paraffins, isoparaffins and naphthenes.

Mass spectrometry is very useful in qualitative analysis. Instrumentation for this includes high-resolution spectrometers and combination units consisting of a gas chromatograph linked to a mass spectrometer.

Mass spectrometers are commercially available with resolutions of one part in 50000 and greater. With these instruments it is possible to examine high-boiling fractions for specific compound types, and in conjunction with low-voltage mass spectrometry, they have been used very successfully for the identification of oxygen-, sulfur- and nitrogen-containing compound. High-resolution mass spectrometry is also extremely useful for obtaining structural information on relatively pure compounds.

The direct coupling of a gas chromatograph to a mass spectrometer (GC/MS) has resulted in an extremely powerful tool for the characterization of complex mixtures. Individual peaks in a chromatogram can usually be identified by their mass spectrum. GC/MS has been used in the identification of contaminants in feedstreams at the parts per million level, for the complete characterization of naphthas which can have over 250 peaks in their gas chromatograms, and for determining isomer distribution in products from experimental isomerization or reforming reactors.

A technique called nitric oxide ionization spectrometry evaluation (NOISE, though it really is more of a modification to the standard GC/MS methods) has gained some popularity in the 1990s for petroleum distillates in the range of 250–1000 °F (120–540 °C). In the NOISE method, bp fractions are bombarded with NO⁺ ions. A mass spectrometer is used to identify the individual components and reports them by carbon number as well as
as by hydrogen deficiency. Knowing these two quantities for all detected components mathematically allows for a PIANO and sulfur analysis of the sample at hand. A drawback of this method is its relatively poor accuracy when applied to C_6 and C_7 hydrocarbons, so that this lighter naphtha has to be removed (easily done by several methods but GC is usually the most readily made automatic) first. It is also helpful to break down a full range cut into several subcuts for separate sequential analysis to improve the accuracy.

Here are some additional standards that may be applicable in the use of mass spectrometry analysis of regulated fuel components:

- ASTM D-1658 – Carbon Number Distribution of Aromatic Compounds in Naphthas by Mass Spectrometry, Standard Practice
- ASTM D-2498 – Isomer Distribution of Straight-chain Detergent Alkylate By Mass Spectrometry, Standard Practice
- ASTM D-2567 – Molecular Distribution Analysis for Monoalkylbenzenes by Mass Spectrometry, Standard Method
- ASTM D-2789 – Hydrocarbon Types in Low Olefinic Gasoline By Mass Spectrometry, Standard Test Method
- ASTM-E899 – Records Management in Mass Spectrometry Laboratories Performing Analysis in Support of
- Patent-5461235 – Mass Spectrometry Apparatus and Method Relating Theretofore
- Patent-5481108 – Method for Ion Detection and Mass Spectrometry and Apparatus Thereof
- ASTM D-2425 – Hydrocarbon Types in Middle Distillates by Mass Spectrometry, Standard Test Method for
- ASTM D-2650 – Chemical Composition of Gases by Mass Spectrometry, Standard Test Method for

6.5 Volatility Measurements

Volatility is a primary factor in liquid fuel quality. The vaporizing tendencies of all types of fuels are important to their combustion characteristics and general utilization. Volatility is also of considerable significance to the quality of other liquid petroleum products, for example, solvents and lubricants.

For some purposes it is necessary to have information on the initial stage of vaporization. To supply this information, flash fire, vapor pressure, and evaporation tests are available. The data from the early stages of the several distillation tests are useful also. In some applications it is important to know the tendency of a product to vaporize partially or completely at ambient temperatures.

6.5.1 Flash and Fire

The flash point of a petroleum product is the temperature to which the product must be heated under the prescribed conditions of the test to give sufficient vapor to form a mixture with air that can be ignited by a suitable flame. The fire point is the temperature at which the oil's vapor ignites and continues to burn for 5 s. If the flash point is known there is additional value in knowing its fire point. The importance of flash point data has led to the development of standardized procedures, including ASTM D-56, D-92, and D-93.

Petroleum products vary widely in flash and fire points. Gasolines flash well below freezing. Solvents, have flash points ranging from below 21 °C (70 °F) up to 52 °C (125 °F). Kerosines flash at 38 °C (100 °F) to 66 °C (150 °F), while heavier fuel oils flash from 66 °C to 121 °C (250 °F). Lubricating oils have flash points from 275 to 700 °F (135–370 °C). Fire points range from 5.5 °C (10 °F) to 22 °C (70 °F) higher than the flash points, with the greater spread appearing in the heavier products. When the flash point is given, the method used in determining it should be mentioned.

The Cleveland open-cup (ASTM D-92) method, the one almost universally used, employs a brass cup supported by a metal ring, see Figure 12. A flame or electric heater under the cup heats the oil sample, in which the bulb of a thermometer is immersed. A tiny pilot flame is moved over the surface of the heated oil at every 5 °F (2.8 °C) rise in temperature. When the vapor above the oil flashes, the temperature reading indicates the flash point of the oil. Theoretically, it is possible to test the whole range of petroleum products with a single flash test. In actual practice it has been better to use three instruments because flash points of petroleum products vary over a wide range. The tag closed tester (ASTM D-56) is used to test all mobile liquids that flash below 79 °C, but not for products classed as fuel oil. The Pensky–Martens closed tester (ASTM D-93) is used to test diesel and heating fuel oil unless other methods are specified. The open cup tester (ASTM D-92) is used for determining both flash and fire point for all petroleum products except fuel oil and those which have a flash point below 79 °C (175 °F).

Flash points are most generally used to determine fire and explosion hazards. For products with flash points below 33 °C (90 °F), special precautions are necessary for
safe handling. Products having flash points in the 33 °C to 66 °C range may also present problems with respect to safe handling and storage. Products with flash points above 66 °C are relatively safe to handle and, in this case, flash points are generally determined as indirect measures of some other quality. For example, flash point is often used by manufacturers and marketers of petroleum products to detect contamination or as an aid in identifying a particular petroleum product.

6.5.2 Reid Vapor Pressure

6.5.2.1 Bomb Methods The RVP apparatus consists essentially of a double-chambered bomb. The upper chamber is fitted with a pressure gage and contains atmospheric air. The lower chamber which has 0.25 the capacity of the upper chamber is filled with a sample of the liquid to be tested. Both the sample and its chamber are first chilled to reduce premature evaporation. The bomb is then sealed, care being taken to prevent the introduction of abnormal pressures.

The sealed bomb is immersed in a 38 °C (100 °F) bath. To assure a maximum opportunity for evaporation, the bomb is removed from the path periodically for brief but vigorous shaking. During this process, a small portion of each fraction is vaporized, the amount depending upon its vapor pressure at test temperature and its concentration in the sample. When an equilibrium is reached, that is, when two consecutive gage readings are identical, that gage reading is recorded as the “uncorrected vapor pressure”.

The bomb pressure consists of the atmospheric pressure plus the sum of the individual vapor pressures of the fractions, each modified according to the ratio of its liquid volume to the total liquid volume. Obviously, this pressure is greater than atmospheric but since the gage registers only pressures above atmospheric, its reading is related only to vapor pressure.

The gage is removed from the bomb, calibrated against a mercury manometer at the value of the uncorrected vapor pressure and any discrepancy noted. The uncorrected value is then corrected for both the gage calibration and the change in the pressure of the water vapor and air in the air chamber between the initial air temperature and 38 °C.

The discussion above is the traditional D-323 method of analysis. Since the water vapor pressure in the vapor over oxygenated fuels is affected by the presence of that oxygenate, D-4953 has its own set of corrections to be made to the “uncorrected cell vapor pressure”.

6.5.2.2 Minicell Methods Since the bomb methods are slow and time consuming, several alternate methods and equipment have been developed to determine vapor pressure of gasoline samples. These were developed with ease of in-field certification in mind.

Portable Cell Test Apparatus. The type of apparatus suitable for use in this test method employs a small volume test chamber incorporating a transducer for pressure measurements and associated equipment for thermostatically controlling the chamber temperature and for evacuating the test chamber prior to sample introduction. It is often generically called a Grabner cell apparatus after one of the first and most prominent vendors of such portable test equipment. Several other vendors have good equipment on the market as well, but the naming sticks, much as Xerox and Coke, describe a wide class of photostatic copiers or cola drinks.

The test chamber contains between 5 and 50-mL of liquid and is capable of containing a vapor-to-liquid ratio of 1.0 up to 4.0 (minimum by standard). A known volume of chilled air-saturated sample is introduced into the evacuated thermostatically controlled test chamber. The internal volume of the test chamber is five times that of the total test specimen introduced into the chamber. After injection into the test chamber, the test specimen is allowed to reach thermal equilibrium at the test temperature, 37.8 °C (100 °F). The resulting rise in pressure in the chamber is measured using a pressure transducer sensor and indicator. Only total pressure
measurements (sum of the partial pressure of the sample and the partial pressure of the dissolved air) are used in this test method, although some instruments can measure the absolute pressure of the sample as well.

The measured total vapor pressure is converted to a dry vapor pressure equivalent (DVPE) by use of a correlation equation. A correction to this value is necessary to account for the biases between the cell pressure and that which would be measured by standard D-4953 laboratory testing. The 1991 ASTM D-2.02 Round Robin test report mentions several correcting equations.

**Automatic Cell Test Method.** The chilled sample cup of the automatic vapor pressure instrument is filled with chilled sample and is coupled to the instrument inlet fitting. The sample is then automatically forced from the sample chamber to the expansion chamber where it is held until thermal equilibrium at 37.8°C (100°F) is reached. In this process the sample is expanded to five times its volume (4:1 vapor-to-liquid ratio). The vapor pressure is measured by a pressure transducer.

The measured vapor pressure is automatically converted to a DVPE value by the instrument. A correction to this value is necessary to account for the observed bias between the test result and that obtained by Test Method D 4953.

The instrument automatically calculates the DVPE from the measured total pressure by means of the following correction equation to correct for the relative bias, found in the 1991 ASTM D-202 Round Robin test program, between the results obtained by this test method and the dry vapor pressure values measured in accordance with Test Method D 4953 as follows, Equation (5):

\[
\text{DVPE (kPa)} = (0.941 \times X) + 3.22 \quad \text{or} \\
\text{DVPE (psi)} = (0.941 \times X) + 0.467
\]

where \(X\) is the measured total pressure in kilopascals (pounds-force per square inch).

### 7 APPLICABLE REGULATORY MEASUREMENT STANDARDS BY CRITERIA COMPONENT\(^{(41,47)}\)

#### 7.1 Introduction

This section presents a more detailed listing and discussion of several of the more commonly recognized standards for analysis of fuels constituents for environmental regulatory reasons. It covers the major standards for North America and the EU, as these areas are furthest advanced in environmental concerns. US EPA and EU regulatory standards are the foundation for environmental regulations in much of the rest of the world, even if enforcement in some of these areas lags behind the developed world.

The standards mentioned in this section are not repeated verbatim. The reader can easily obtain these directly and inexpensively, as needed, from either ASTM or ANSI/ISO. In fact, since these standards are routinely updated by several diligent industrial and government committee representatives, any detailed coverage discussed here is likely to be obsolete within a few years.

The content of these standards varies greatly. In some cases, procedures for using specific analytical equipment are provided in great detail, along with illustrations and lots of minutiae. In other cases, they only detail the allowable limits and provide an official “accuracy” statement of a given type of analytical procedure for a specific type of measurement on a certain type of fuel product stream. Statistical reliability metrics, calibration standards, and sample preparation methods are three of the most common areas of coverage that these methods provide.

Analytical instrument vendors typically provide “off the shelf” systems that are calibrated and verified to one or more of several appropriate standards and analytical environments. ISO 9000 and ISO 14000 requirements for commercial and environmental compliance equipment are fairly strict in removing human error as much as possible from the sampling and measurement process. An IR spectroscopy-based standard may provide a one way of interpreting a spectral chart for a certain composition of sample material and another for a different type of sample. Modern analyzers not only take the spectra, but also calculate the necessary information from digital analysis of the spectral pattern. (The days of doing graphical integration of peak charts by hand – literally counting chart crosshatching scale squares – are over.) To change from one standard methodology to another is often now a matter of choosing a different methodology on a Microsoft Windows™-based computer interface dialog box and hitting the return key on a keyboard. ISO 9000 manufacturing compliance also sets some fairly strong legal requirements for calibration of a piece of test equipment to prevailing standards.

The typical standard values stated in the SI (Système International d‘Unités) units are to be regarded as the standard conversion. Conversion to and from these units to English-language engineering values may or may not be covered. A few of the standards even specify the precision with which such conversions should be reported! In most cases, normal prevailing laboratory practices for accuracy and precision of reported numbers are more than adequate to maintain adherence to the standard. If in doubt, there are even standards for laboratory practice standards that can be consulted.
None of the standards address any safety issues, if any, associated with its use. It is the responsibility of the user of the standard to establish appropriate safety and health practices and determine the applicability of regulatory limitations prior to use.

7.2 Choosing the Appropriate Standards

With the availability of several perfectly valid alternatives for obtaining chemical analyses, how should one determine which one(s) to use. This may be as simple an answer as referring to the local regulatory agencies’ codified requirements. Usually, they present alternatives as well. In some cases, multiple regulatory governing bodies have conflicting specifications.

Table 13 lists the adopted and equivalent test methods for the CARB components whose designated test methods have recently been amended. It should be noted that certain conditions must be met when using the equivalent test methods for aromatic hydrocarbons (aromatics) and low level (1–10 ppm) sulfur.

In fact, each refiner is free to control and do analysis by whatever method they feel comfortable with. Whatever is measured and however the numbers are obtained, they must provide answers compatible with whatever the local governing agencies (all of them) have deemed as the standard of choice.

7.3 Distillation Methodology

7.3.1 D86 Distillation of Petroleum Products

This test method covers the distillation of natural gasolines, motor gasolines, aviation gasolines, aviation turbine fuels, special boiling point spirits, naphthas, white spirit, kerosines, gas oils, distillate fuel oils, and similar petroleum products, utilizing either manual or automated equipment. It is the most widely used distillation standard for naphtha-containing fuels. There is some question about its accuracy with diesel range petroleum fractions but most distillations of this material are reported as D86 or its equivalent from a related test.

7.3.2 D3710 Boiling Range Distribution of Gasoline and Gasoline Fractions by Gas Chromatography

This test method covers the determination of the boiling range distribution of gasoline and gasoline components. This test method is applicable to petroleum products and fractions with a FBP of 500°F (260°C) or lower as measured by this test method. D3710 is designed to measure the entire boiling range of gasoline and gasoline components with either high or low RVP and is commonly referred to as GC distillation. It is essentially a GC-equivalent procedure to obtain D86 assay information. D-3710 has not been validated for gasolines containing oxygenated compounds (for example, alcohols or ethers).

7.3.3 D1160 Distillation of Petroleum Products at Reduced Pressure

This test method covers the determination, at reduced pressures, of the range of boiling points for petroleum products that can be partially or completely vaporized at a maximum liquid temperature of 400°C. Both a manual method and an automatic method are specified. It is not really suitable for gasoline or kerosine but may be for heavier diesel stocks. It is also not amenable to on-line

<sup>a</sup> ACEA, Association des Constructeurs Européens de l’Automobile.

<sup>b</sup> FBP.
analysis as it is clumsy to perform, though it is simpler than TBP (true boiling point). D1160 values can be reasonably converted to TBP and thence to equivalent D86 values via the API Technical Databook.[(75)]

7.3.4 D2887-e1 Boiling Range Distribution of Petroleum Fractions by Gas Chromatography
This test method covers the determination of the boiling range distribution of petroleum products. D2887 is applicable to petroleum products and fractions having a FBP of 538°C (1000°F) or lower at atmospheric pressure as measured by this test method. It is limited to samples having a boiling range greater than 55°C (176°F), and having a vapor pressure sufficiently low to permit sampling at ambient temperature. It is not to be used for the analysis of gasoline samples or gasoline components, which should be analyzed by Test Method D3710.

7.3.5 D2892 Distillation of Crude Petroleum (15-Theoretical Plate Column)
D2892 describes the procedure for the distillation of stabilized crude petroleum to a final cut temperature of 400°C AET (atmospheric equivalent temperature). The test method employs a fractionating column having an efficiency of 14 to 18 theoretical plates operated at a reflux ratio of 5:1. Performance criteria for the necessary equipment is specified. Some typical examples of acceptable apparatus are presented in schematic form. This test method offers a compromise between efficiency and time in order to facilitate the comparison of distillation data between laboratories. It is commonly referred to as “standard” TBP distillation. Although only indirectly related to most gasoline volatility standards, the standard contains a wealth of information. TBP values have the property of being blendable in linear fashion without a severe loss of accuracy. D86 and other ASTM assay methods are not so readily predictable for multiple blended cuts TBP values can be reasonably converted to and from D86, D1160, and D2887 values via the API Technical Databook Method 3A1.1.

The test method gives details of procedures for the production of a liquefied gas, distillate fractions and residuum of standardized quality on which analytical data can be obtained, and the determination of yields of the above fractions by both mass and volume. From the above information a graph of temperature versus mass-percent distilled can be produced. This distillation curve corresponds to a laboratory technique which is defined at 15/5 (15 theoretical plate column, 5:1 reflux ratio) or TBP.

This test method can also be applied to any petroleum mixture except LPGs, very light naphthas, and fractions having IBPs above 400°C.

D2892 contains the following Annexes:
- Annex A4 – Test Method for the Verification of Temperature Sensor Location
- Annex A6 – Practice for the Calibration of Sensors
- Annex A7 – Test Method for the Verification of Reflux Dividing Valves
- Annex A8 – Test Method for Dehydration of a Sample of Wet Crude Oil
- Annex A9 – Conversion of Observed Vapor Temperature to atmospheric equivalent temperature (AET)
- Annex A10 – Practice for Performance Check

7.3.6 D5307 Determination of Boiling Range Distribution of Crude Petroleum by Gas Chromatography
This test method covers the determination of the boiling range distribution of water-free crude petroleum through 538°C (1000°F). Material boiling above 538°C is reported as residue. D-5307 is applicable to whole crude samples that can be solubilized in a solvent to permit sampling by means of a microsyringe.

7.3.7 D1078-95 Distillation Range of Volatile Organic Liquids
This test method covers the determination of the distillation range of liquids boiling between 30 and 350°C, which are chemically stable during the distillation process. D-1078 is applicable to organic liquids such as hydrocarbons, oxygenated compounds, chemical intermediates, and blends thereof. Typically this has been replaced by the D-86 standard.

7.3.8 Nonstandard Distillation Methods – High-temperature Extended Simulated Distillation
A few simulated distillation GC vendors have equipment to extend the range of the GC/SEMBIST standards above by high-temperature simulated distillation (HTSD). This relatively new method which extends ASTM D-2887 determination of the boiling range distribution of hydrocarbons to a FBP of about 1400°F (760°C). The use of capillary GC column and stationary phase technology advances,
together with either programmed temperature vaporization (PTV) or on-column injection techniques, provides adequate separation of from C₅ to C₂₀ normal paraffins allowing the characterization of petroleum products from about 97 to 1380 °F (36–750 °C).

7.4 V/L Methodology

7.4.1 D2533 Vapor–Liquid Ratio of Spark-ignition Engine Fuels

This test method covers a procedure for measuring the volume of vapor formed at standard atmospheric pressure from a given volume of gasoline. The ratio of these volumes is expressed as the vapor–liquid (V/L) ratio of the gasoline at the temperature of the test.

Dry glycerol can be used as the containing liquid for nonoxygenated fuels. Mercury can be used as the containing liquid with both oxygenated and nonoxygenated fuels. Because oxygenates in fuels may be partially soluble in glycerol, gasoline–oxygenate blends must be tested using mercury as the containing fluid. Test Method D-4815 can be used to determine the presence of oxygenates in fuels first.

7.4.2 D5188 Vapor–Liquid Ratio Temperature Determination of Fuels (Evacuated Chamber Method)

D-5188 covers the determination of the temperature at which the vapor formed from a selected volume of volatile petroleum product saturated with air at 0–1 °C (32–34 °F) produces a pressure of one atmosphere in an evacuated chamber of fixed volume. It is applicable to samples for which the determined temperature is between 36 and 80 °C (97 and 176 °F) and the vapor–liquid ratio is between 8 to 1 and 75 to 1.

When the vapor–liquid ratio is 20:1, the result is intended to be comparable to the results determined by Test Method D-2533. This test method may also be applicable at pressures other than one atmosphere, but the stated precision may not apply. It is, however, applicable to both gasoline and gasoline–oxygenate blends.

Other standards of possible use in distillation and V/L analysis of regulated fuel components are:

- ASTM D-216 – Distillation of Natural Gasoline, Standard Method for. This is now supplanted mostly by D-86 on stabilized naphthas from NGL recovery plants
- ASTM-E1405 – Laboratory Glass Distillation Flasks, Standard Specification for
- ISO-918 – Volatile Organic Liquids for Industrial Use – Determination of Distillation Characteristic
- ASTM D-1093 – Acidity of Hydrocarbon Liquids and Their Distillation Residues, Standard Test Method for
- ISO 3405 Petroleum products – Determination of Distillation Characteristics

7.5 Measurement of Reid Vapor Pressure – Gasoline Products

7.5.1 D323 Vapor Pressure of Petroleum Products (Reid Method)

This is the original RVP test standard. This test method covers four procedures for the determination of vapor pressure of gasoline, volatile crude oil, and other volatile petroleum products. Procedure A is applicable to gasoline and other petroleum products with a vapor pressure of less than 180 kPa (26 psi). Procedure B may also be applicable to these other materials, but only gasoline was included in the interlaboratory test program to determine the precision of this test method. Neither procedure is applicable to liquefied petroleum gases or fuels containing oxygenated compounds other than MTBE or alcohols. Procedure C is for materials with a vapor pressure of greater than 180 kPa (26 psi) and Procedure D for aviation gasoline with a vapor pressure of approximately 50 kPa (7 psi).

Because the external atmospheric pressure is counteracted by the atmospheric pressure initially present in the vapor chamber, the RVP is an absolute pressure at 37.8 °C (100 °F) in kilopascals (pounds-force per square inch). The RVP differs from the true vapor pressure of the sample because of some small sample vaporization and the presence of water vapor and air in the confined space. It is not suitable for use with oxygenated fuels. For determination of the vapor pressure of gasoline–oxygenate blends, refer to Test Method D4953.

7.5.2 D4953 Vapor Pressure of Gasoline and Gasoline–Oxygenate Blends (Dry Method)

This test method, a modification of test Method D323 (Reid method), provides two procedures to determine the vapor pressure of gasoline and gasoline–oxygenate blends. Again, because the external atmospheric pressure is counteracted by the atmospheric pressure initially present in the air chamber, this vapor pressure is an absolute pressure at 37.8 °C (100 °F) in kilopascals (pounds-force per square inch). This vapor pressure differs from the true vapor pressure of the sample because of some small vaporization of the sample and air in the confined space.
D4953 is applicable to gasolines and gasoline–oxygenate blends with a vapor pressure range from 35 to 100 kPa (5–15 psi). Vapor pressure of gasoline or gasoline–oxygenate blends below 35 kPa (5 psi) or greater than 100 kPa (15 psi) can be determined with D4953, but the precision and bias as described in section 10 of the standard do not apply. For materials with a vapor pressure greater than 100 kPa (15 psi), use the 0 to 200 kPa (0–30 psi) gage as specified in the Annex of Test Method D323.

7.5.3 D5190 Vapor Pressure of Petroleum Products (Automatic Method)

D5190 covers the determination of the total pressure of air-containing volatile petroleum products. It is suitable for testing samples with bps above 0 °C (32 °F) that exert a vapor pressure between 7 and 172 kPa (1 and 25 psi) at 37.8 °C (100 °F) at a vapor-to-liquid ratio of 4:1. This test method is suitable for testing gasoline samples that contain oxygenates. No account is taken of dissolved water in the sample.

This test method is suitable for the calculation of a DVPE by means of a correlation equation (see section 6.5.2.2). The calculated DVPE very closely approximates the dry vapor pressure that would be obtained on the same material when tested in accordance with test Method D4953.

7.5.4 D5191 Vapor Pressure of Petroleum Products (Mini Method)

D5191 covers the use of automated vapor pressure instruments to determine the total vapor pressure exerted in vacuum by air-containing volatile liquid petroleum products. This test method is suitable for testing samples with bps above 0 °C (32 °F) that exert a vapor pressure between 7 and 130 kPa (1.0 and 18.6 psi) at 37.8 °C (100 °F) at a vapor-to-liquid ratio of 4:1. Measurements are made on liquid sample sizes in the range of 1–10 mL. No account is taken of dissolved water in the sample. Samples can also be tested at other vapor-to-liquid ratios, temperatures, and pressures, but the precision and bias statements need not apply.

D5191 is suitable for calculation of the DVPE of gasoline and gasoline–oxygenate blends by means of a linear correlation equation. The calculated DVPE very closely approximates the dry vapor pressure that would be obtained on the same material when tested by test Method D-4953.

7.5.5 D5482 Vapor Pressure of Petroleum Products (Mini Method–Atmospheric)

This test method provides a procedure for the determination of total vapor pressure of petroleum products using automatic vapor pressure instruments. The test method is suitable for testing samples with bps above 0 °C (32 °F) that exert a vapor pressure between 7 and 110 kPa (1.0 and 16 psi) at 37.8 °C (100 °F) at a vapor-to-liquid ratio of 4:1. D5482 is applicable to gasolines containing oxygenates. No account is taken of dissolved water in the sample.

Because the external atmospheric pressure does not influence the resultant vapor pressure, this vapor pressure is an absolute pressure at 37.8 °C (100 °F) in kPa (psi). This vapor pressure differs from the true vapor pressure of the sample because of some small vaporization of the sample and dissolved air into the air of the confined space.

The D-5482 test is a modification of Test Method D5191 (mini method) where the test chamber is at atmospheric pressure prior to sample injection. It covers the use of automated vapor pressure instruments that perform measurements on liquid sample sizes in the range from 1 to 10 mL. D5482 is also suitable for the determination of the Test Method D4953 DVPE of gasoline and gasoline–oxygenate blends by means of a correlating equation.

7.5.6 D2889 Calculation of True Vapor Pressures of Petroleum Distillate Fuels

This test method describes the calculation of true vapor pressures of petroleum distillate fuels for which data may be obtained in accordance with Test Method D-86 without reaching a decomposition point prior to obtaining 90 volume% distilled. D-2889 may be used to calculate vapor pressures at temperatures between the 0% equilibrium flash temperature and the critical temperature of the fuel. Provisions are included for obtaining a calculated critical temperature for fuels for which it is not known.

The method is not reliable for distillate fuels having a boiling range of less than 100 °F (38 °C) between the ASTM Test Method D-86 10 and 90 volume% distilled temperatures.

Other applicable standards for RVP analysis are found in:
- ISO 3007 Petroleum Products – Determination of Vapor Pressure – Reid method

7.6 Detection and Measurement of Aromatics – Gasoline/Avgas Cuts

7.6.1 D5580-95 Determination of Benzene, Toluene, Ethylbenzene, p/x-Xylene, o-Xylene, C9 and Heavier Aromatics, and Total Aromatics in Finished Gasoline by Gas Chromatography

D5580 covers the determination of benzene, toluene, ethylbenzene, the xylenes, C9 and heavier aromatics, and total aromatics in finished motor gasoline by
GC. The aromatic hydrocarbons are separated without interferences from other hydrocarbons in finished gasoline. Nonaromatic hydrocarbons that have a bp greater than n-dodecane may cause interference with the determination of the C₈ and heavier aromatics. For the C₈ aromatics, o-xylene and m-xylene co-elute, while ethylbenzene and xylene are separated. The C₉ and heavier aromatics are determined as a single group.

This test method covers the following concentration ranges, in liquid volume %, for the preceding aromatics: benzene, 0.1–5%; toluene, 1–15%; individual C₈ aromatics, 0.5–10%; total C₉ and heavier aromatics, 5–30%, and total aromatics, 10–80%. Results are reported to the nearest 0.01% by either mass or by liquid volume.

Many of the common alcohols and ethers that are added to gasoline to reduce carbon monoxide emissions and increase octane, do not interfere with the analysis. Ethers such as MTBE, ETBE, TAME, and diisopropyl ether (DIEP) have been found to elute from the precolumn with the nonaromatic hydrocarbons to vent. Other oxygenates, including methanol and ethanol, elute before benzene and the aromatic hydrocarbons. 1-Methylcyclopentene has also been found to elute from the precolumn to vent and does not interfere with benzene.

7.6.2 D5769 Determination of Benzene, Toluene, and Total Aromatics in Finished Gasolines by Gas Chromatography/Mass Spectrometry

This test method covers the determination of benzene, toluene, and total aromatics in finished motor gasoline, including RFG containing oxygenated blending components, by GC/MS. It is applicable to the following concentration ranges, in liquid volume %, for the following aromatics: benzene 0.1–3%; toluene 1–15%; and total (C₉–C₁₂) aromatics 10–40%. D-5769 has not been tested by ASTM for gasoline samples containing a concentration of uncalibrated C₁₀–C₁₂ aromatic compounds greater than approximately 3 volume %. Also, the test method has not been tested by ASTM for individual hydrocarbon process streams in a refinery, such as reformates, fluid catalytic cracked naphthas, and so on, used in blending of gasolines.

Results are reported to the nearest 0.01% for benzene and 0.1% for the other aromatics by either mass or liquid volume.

7.6.3 D4420-94 Determination of Aromatics in Finished Gasoline by Gas Chromatography

The D4420 test method provides for the determination of benzene, toluene, C₈, C₉ and heavier aromatics, and total aromatics in finished motor gasoline. It is also applicable to gasoline blending components. For analysis of gasolines for benzene and toluene, solely, test Method D-3606 is appropriate.

D-4420 is applicable to the following concentration ranges, in liquid volume percent, for the individual aromatics listed above: benzene, 0.1–5; toluene, 1–20; C, 5–25; C and heavier, 5–30, and total aromatics, 10–80. Results are reported to the nearest 0.1% by liquid volume.

D4420 is slightly more accurate than D-5580, but it has not been determined whether this test method is applicable to gasoline containing oxygenates.

7.6.4 D3257-e1 Aromatics in Mineral Spirits by Gas Chromatography

These test methods cover the determination of ethylbenzene and total eight-carbon (C₈) and heavier aromatics in the concentration range from 0.1 to 30% in mineral spirits having a distillation range from 149 to 210°C (300–410°F) as determined by Test Method D86. The procedures permit the identification and calculation of concentrations of aromatic components to 0.1 volume %.

Oxygenated compounds, if present, may interfere and cause erroneous results. Such oxygenated compounds are not normally present in mineral spirits. Two test methods are covered as follows:

- Test Method A, measurement of ethylbenzene content, C plus higher aromatics (except ethylbenzene), and total aromatics by means of a single GC analysis.
- Test Method B, measurement of ethylbenzene content by means of a rapid GC analysis.

7.6.5 D5292 Aromatic Carbon Contents of Hydrocarbon Oils by High Resolution Nuclear Magnetic Resonance Spectroscopy

D-5292 covers the determination of the aromatic hydrogen content (Procedures A and B) and aromatic carbon content (Procedure C) of hydrocarbon oils using high-resolution NMR spectrometers. Applicable samples include kerosines, gas oils, mineral oils, lubricating oils, coal liquids, and other distillates that are completely soluble in chloroform and carbon tetrachloride at ambient temperature. For pulse Fourier transform spectrometers, the detection limit is typically 0.1 mol% aromatic hydrogen atoms and 0.5 mol% aromatic carbon atoms. For continuous wave (CW) spectrometers, which are suitable for measuring aromatic hydrogen contents only, the detection limit is considerably higher and typically 0.5 mol% aromatic hydrogen atoms.

The reported units are mole percent aromatic hydrogen atoms and mole percent aromatic carbon atoms. This test method is not applicable to samples containing more than 1 mass % olefinic or phenolic compounds, and neither does it cover the determination of the percentage mass of aromatic compounds in oils, since NMR signals from both saturated hydrocarbons and aliphatic substituents...
on RA compounds appear in the same chemical shift region. For the determination of mass or volume percent aromatics in hydrocarbon oils, chromatographic, or mass spectrometry methods can be used.

7.6.6 D5776 Bromine Index of Aromatic Hydrocarbons by Electrometric Titration
This test method determines the amount of bromine-reactive material in aromatic hydrocarbons and is thus a measure of trace amounts of unsaturates in these materials. It is applicable to materials having bromine indexes below 500.

The D-5776 standard is applicable to aromatic hydrocarbons containing no more than trace amounts of olefins and that are substantially free from material lighter than isobutane and have a distillation EP under 288 °C (550 °F)

7.6.7 D2789 Hydrocarbon Types in Low-olefinic Gasoline by Mass Spectrometry
This test method discusses the determination by mass spectrometry of the total paraffins, monocycloparaffins, bicycloparaffins, alkylbenzenes, indans or tetralins or both, and naphthalenes in gasoline which have an olefin content of less than 3 volume% and a 95% distillation point of less than 210 °C (411 °F) as determined in accordance with Test Method D-86. Olefins are determined by Test Method D-1319, or by Test Method D-875. It has not been determined if D2789 is sufficiently applicable to gasolines containing oxygenated compounds (for example, alcohols and ethers).

7.7 Detection and Measurement of Aromatics – Turbine and Diesel Fuels

7.7.1 D2549 Separation of Representative Aromatics and Nonaromatics Fractions of High-boiling Oils by Elution Chromatography
D-2549 methodology covers the separation and determination of representative aromatics and nonaromatics fractions from hydrocarbon mixtures that boil between 232 and 538 °C (450 and 1000 °F). Alternative procedures are provided for the separation of 2 g or 10 g of hydrocarbon mixture. Some components may not be eluted from the chromatographic column for some types of sample under the conditions used in this method. It is not applicable to gasoline range cuts.

Test Method D-2007 is an alternative method of separating high-boiling oils into polar compounds, aromatics, and saturates fractions.

7.7.2 D2425 Hydrocarbon Types in Middle Distillates by Mass Spectrometry
This test method covers an analytical scheme using the mass spectrometer to determine the hydrocarbon types present in virgin middle distillates 204–343 °C (400–650 °F) boiling range, 5–95 volume% as determined by Method D86. Samples with an average carbon number value of paraffins between C12 and C16 and containing paraffins from C10 and C18 can be analyzed. Eleven hydrocarbon types are determined. These include paraffins, noncondensed cycloparaffins, condensed dicycloparaffins, condensed tricycloparaffins, alkylbenzenes, indans or tetralins, or both, CnH2n−10 (indenes, etc.), naphthalenes, CnH2n−14 (acenaphthenes, etc.), CnH2n−16 (acenaphthylene, etc.), and tricyclic aromatics.

7.8 General Ponaffin, Isoponaffin, Aromatic, Naphthene, Olefin Analyses for Aromatics and Other Components

7.8.1 D3238 Calculation of Carbon Distribution and Structural Group Analysis of Petroleum Oils by the n-d-M Method
D3238 discusses the calculation of the carbon distribution and ring content of olefin-free petroleum oils from measurements of refractive index, density and molecular weight (n-d-M). This test method should not be applied to oils whose compositions are outside the following ranges: in terms of carbon distribution – up to 75% carbon atoms in ring structure; percentage in RA not larger than 1.5 times the percentage in naphthenic rings; in terms of ring content – one can have up to four rings per molecule, with not more than half of them aromatic. A correction must be applied for oils containing significant quantities of sulfur.

The composition of complex petroleum fractions is often expressed in terms of the proportions of RA, naphthene rings (RN) and paraffin chains (CP) that would comprise a hypothetical mean molecule. Alternatively, the composition may be expressed in terms of a carbon distribution, that is, the percentage of the total number of carbon atoms that are present in RA structures (% CA), naphthene ring structures (% CN) and in CP (% CP).

7.8.2 D5134 Detailed Analysis of Petroleum Naphthas Through n-Nonane by Capillary Gas Chromatography
This test method covers the determination of hydrocarbon components of petroleum naphthas. Components eluting after n-nonane (bp 150.8 °C) are determined as a single group. Components that are present at the 0.05 mass % level or greater can be determined.

D5134 applies to olefin-free (<2% olefins by liquid volume) liquid hydrocarbon mixtures including virgin naphthas, reformates, and alkylates. Olefin content can be determined by Test Method D1319. The hydrocarbon mixture must have a 98% distillation point of 250 °C or less as determined by Test Method D3710.
7.8.3 D5443 Paraffin, Naphthene, and Aromatic Hydrocarbon-type Analysis in Petroleum Distillates through 200°C by Multidimensional Gas Chromatography

This test method provides for the determination of paraffins, naphthenes, and aromatics by carbon number in low-olefinic hydrocarbon streams which have FBPs of 200 °C or less. Hydrocarbons with bps greater than 200 °C and less than 270 °C are reported as a single group. Olefins, if present, are hydrogenated and the resultant saturates are included in the paraffin and naphthene distribution. Aromatics boiling at C9 and above are reported as a single aromatic group.

D5443 was not intended to determine individual components except for benzene and toluene that are the only C6 and C7 aromatics, respectively, and cyclopentane, which is the only C5 naphthene. The lower limit of detection for a single hydrocarbon component or group is 0.05 mass%. This test method is applicable to hydrocarbon mixtures including virgin, catalytically converted, thermally converted, alkylated and blended naphthas.

Some other standards and reference sources for aromatics analyses in hydrocarbon fuels are:

- API-4439 – Exposure Data on C7 and C8 Aromatics During Handling and Production of Motor Gasolines
- ASTM D-2267 – Aromatics in Light Naphthas and Aviation Gasolines by Gas Chromatography, Standard Test
- ASTM D-875 – Calculation of Olefins and Aromatics in Petroleum Distillates from Bromine Number and Acid a°
- ISO 2549 – Separation of Representative Aromatics and Nonaromatics Fractions of High Boiling Oils by Elution Chromatography.

7.9 Detection and Measurement of Benzene

7.9.1 D3606 Determination of Benzene and Toluene in Finished Motor and Aviation Gasoline by Gas Chromatography

This test method provides for a primary standard for the determination of benzene and toluene in finished motor and aviation gasolines by GC. As such, the standard mandates calibrations before routine sample preparation and analysis, all of which adds up to a fairly tedious process. Benzene can be determined between the levels of 0.1 and 5 volume%. It has not been determined whether D3606 is applicable to gasolines containing oxygenated compounds (for example, alcohols or ethers). Ethanol is known to interfere with the benzene determination and some modifications of the GC column to correct for this are being considered.

7.9.2 D4053 Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy

This test method covers the determination of the percent benzene in full-range gasoline. It is applicable to concentrations from 0.1 to 5 volume%. D-4053 has not been validated for gasolines containing oxygenates.

7.9.3 D4534-e1 Benzene Content of Cyclic Products by Gas Chromatography

This test method covers the determination of the benzene content of specific cyclic hydrocarbon products. Benzene may be determined over a range from 5–300 mg kg⁻¹. The products in which benzene can be determined include cyclohexane, toluene, individual C8 aromatics, cumene, and styrene.

Some other standards and reference sources for benzene analysis in hydrocarbon fuels are:

- API-DR-111 – Estimation of Incremental Benzene Exposure Associated with Bulk Gasoline Storage
- API-DR-195 – Naturally Occurring Benzene, Toluene and Xylenes in Soils
- API-DR-221 – Removal of Benzene from Refinery Wastewater
- API-4470-1 – Volume 1: Exhaust Benzene Emissions from Late Model Vehicles
- ASTM D-1017 – Benzene and Toluene in 250°F and Lighter Petroleum Products by Ultraviolet Spectrophotometer
- ASTM D-4053 – Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy, Standard Test Method for
- ASTM D-4367 – Benzene in Hydrocarbon Solvents by Gas Chromatography, Standard Test Method for
- ASTM D-4534 – Benzene Content of Cyclic Products by Gas Chromatography, Standard Test Method for
- ASTM D-4600 – Determination of Benzene-soluble Particulate Matter in Workplace Atmospheres, Standard
- ASTM D-5580 – Determination of Benzene, Toluene, Ethylbenzene, p/x-Xylene, o-Xylene, C9 and Heavier Aromatics
- ASTM D-5769 – Determination of Benzene, Toluene, and Total Aromatics in Finished Gasolines by Gas Chromatography.
See also the above section on aromatics and PIANO analysis standards.

7.10 Detection and Measurement of Olefins

Although no specific recommendations for one method over another is promoted (beyond mentioning the regulatory requirements) in most of section 7, an exception must be made here.

Olefins are a priority control constituent for CARB and US EPA Phase II gasolines. The US EPA has proposed that fuel olefins of ozone-forming potential be measured via the FIA analysis procedures outlined in ASTM D-1319. Several sources, including the author, have noted that FIA olefins for high olefins gasoline blend stocks may be far less accurate than alternative means of measurements.

This applies most to unhydroprocessed thermally cracked streams in a refinery. Chiefly these are FCC and coker light cuts that happen to go to the gasoline pool. The FCC gasoline may have as much as 50% olefinic material, the coker as much as 10%. If it is necessary to control the rates of either of these blend stocks into the blend header with a potential olefins constraint, one should exercise caution in the assumed amount of the stock that will meet all criteria based on linear blend values of properties. A safe option would be to assume 10–15% more olefin in the stock than what is reported by FIA analysis, at least until a detailed biasing study is performed with several months of on-line data available.(76)

7.10.1 D1159 Bromine Numbers of Petroleum Distillates and Commercial Aliphatic Olefins by Electrometric Titration

This test method covers the determination of the bromine number of petroleum distillates that are substantially free of material lighter than isobutane and that have 90% distillation points (by Test Method D-86) under 327 °C (626 °F). This test method is generally applicable to gasoline (including leaded, unleaded and oxygenated fuels), kerosine, and distillates in the gas oil range that fall within the following limits: bromine number at 90% distillation point, under 205 °C (400 °F) = 2 and from 205 to 327 °C (400–626 °F) = 10.

The magnitude of the bromine number is an indication of the quantity of bromine-reactive constituents, not an identification of constituents; therefore, its application as a measure of olefinic unsaturation should not be undertaken without the study given in Annex A1 of the standard.

For petroleum hydrocarbon mixtures of bromine number less than 1.0, a more precise measure for bromine-reactive constituents can be obtained by using Test Method D-2710. If the bromine number is less than 0.5, then Test Method D-2710 or the comparable bromine index methods for industrial aromatic hydrocarbons, Test Method D-1492, must be used in accordance with their respective scopes. The practice of using a factor of 1000 to convert bromine number to bromine index is not applicable to these lower values of bromine number.

7.10.2 D1319-a Hydrocarbon Types in Liquid Petroleum Products by Fluorescent Indicator Adsorption

This test method is for determining hydrocarbon types over the concentration ranges from 5–99 volume% aromatics, 0.3–55 volume% olefins, and 1–95 volume% saturates in petroleum fractions that distill below 315 °C, although some reports sharply limit this effective range. D-1319 may apply to concentrations outside these ranges, but the precision has not been determined. Samples containing dark-colored components that interfere in reading the chromatographic bands cannot be analyzed.

This test method is intended for use with full boiling range products. Comparative data have established that the precision statement does not apply to narrow boiling petroleum fractions near the 315 °C limit. Such samples are not eluted properly, and results are erratic.

The precision statement for this test method has been determined with unleaded fuels that do not contain oxygenated blending components. It may or may not apply to automotive gasolines containing lead antiknock mixtures or oxygenated gasoline blending components, or both.

The following oxygenated blending components: methanol, ethanol, MTBE, TAME and ETBE do not interfere with the determination of hydrocarbon types at concentrations normally found in commercial blends. These oxygenated components are not detected, since they elute with the alcohol desorbent. Other oxygenated compounds must be individually verified. When samples containing oxygenated blending components are analyzed, the results must be corrected to a total-sample basis.

7.10.3 D2710-e1 Bromine Index of Petroleum Hydrocarbons by Electrometric Titration

This test method covers the determination of the amount of bromine-reactive material in petroleum hydrocarbons, and is thus a measure of trace amounts of unsaturates in these materials. It is applicable to materials having bromine indexes below 1000.

The D-2710 test method is applicable only to essentially olefin-free hydrocarbons or mixtures that are substantially free from material lighter than isobutane and have a distillation end point (EP) under 288 °C (550 °F). This procedure has been comparatively tested on materials with bromine indexes in the range from 100 to 1000. These materials include petroleum distillates
such as straight-run and hydrocracked naphtha, reformer feed, kerosine, and aviation turbine fuel. Materials with bromine index greater than 1000 should be tested for bromine number using Test Method D-1159/IP 130. Industrial aromatic hydrocarbons should be tested using Test Method D-1492.

Other possible applicable standards for olefins analysis are:

- ASTM D-875 – Calculation of Olefins and Aromatics in Petroleum Distillates from Bromine Number and Acid
- ISO 3839 Petroleum Products – Determination of Bromine Number of Distillates and Aliphatic Olefins – Electrometric Method

7.11 Detection and Measurement of Sulfur

7.11.1 D1266 Sulfur in Petroleum Products (Lamp Method)

D-1266 covers the determination of total sulfur in liquid petroleum products in concentrations from 0.01 to 0.4 mass% (Note 1). A special sulfate analysis procedure is described in Annex A1 that permits the determination of sulfur in concentrations as low as 5 mg kg⁻¹.

The direct burning procedure (section 9) is applicable to the analysis of such materials as gasoline, kerosine, naphtha, and other liquids that can be burned completely in a wick lamp. The blending procedure (section 10) is applicable to the analysis of gas oils and distillate fuel oils, naphthenic acids, alkyl phenols, high sulfur-content petroleum products, and many other materials that cannot be burned satisfactorily by the direct burning procedure.

Phosphorus compounds normally present in commercial gasoline do not interfere. A correction is given for the small amount of acid resulting from the combustion of the lead antiknock fluids in gasolines. Appreciable concentrations of acid-forming or base-forming elements from other sources interfere when the titration procedure is employed because no correction is provided in these cases.

7.11.2 D2622 Sulfur in Petroleum Products by X-ray Spectrometry

D2622 covers the determination of total sulfur in liquid petroleum products and in solid petroleum products that can be liquefied with moderate heating or dissolved in a suitable organic solvent. The applicable concentration range will vary to some extent with the instrumentation used and the nature of the sample. Optimum conditions will allow the direct determination of sulfur in essentially paraffinic samples at concentrations exceeding 0.0010 mass%.

Methanol containing fuels M-85 and M-100 may be analyzed with an accompanying loss of sensitivity and precision because of the more absorbing matrix caused by the high oxygen content of these fuels. M-85 is 85% methanol–15% gasoline, and M-100 fuel is 100% methanol. Correction factors are applied to achieve these results.

7.11.3 D3227 Mercaptan Sulfur in Gasoline, Kerosine, Aviation Turbine, and Distillate Fuels (Potentiometric Method)

This test method covers the determination of mercaptan in gasolines, kerosines, aviation turbine fuels, and distillate fuels containing from 0.0003 to 0.01 mass% of mercaptan sulfur. Organic sulfur compounds such as sulfides, disulfides, and thiophene do not interfere. Elemental sulfur in amounts less than 0.0005 mass% does not interfere. Hydrogen sulfide will interfere, if not removed.

7.11.4 D4294 Sulfur in Petroleum Products by Energy-dispersive X-ray Fluorescence Spectroscopy

This standard covers the measurement of sulfur in hydrocarbons such as naphthas, distillates, fuel oils, residues, lubricating base oils and nonleaded gasoline. The concentration range is from 0.05 to 5 mass%.

D-4294 applicable tests may involve hazardous materials, operations, and equipment. The standard does not purport to address all of the safety concerns, if any, associated with its use. It is the responsibility of the user of this standard to establish appropriate safety and health practices, and then determine the applicability of regulatory limitations prior to use. For specific precautionary statements, see section 7.

7.11.5 D4952 Qualitative Analysis for Active Sulfur Species in Fuels and Solvents (Doctor Test)

This test method is intended primarily for the detection of mercaptans in motor fuel, kerosine, and similar petroleum products. This test is one of the oldest in the refining industry, but still reasonably accurate.

7.11.6 D5623 Sulfur Compounds in Light Petroleum Liquids by Gas Chromatography and Sulfur-selective Detection

This test method covers the determination of volatile sulfur-containing compounds in light petroleum liquids. It is applicable to distillates, gasoline motor fuels (including
those containing oxygenates) and other petroleum liquids with a FBP of approximately 230°C (450°F) or lower at atmospheric pressure. The applicable concentration range will vary to some extent depending on the nature of the sample and the instrumentation used; in most cases, however, the test method is applicable to the determination of individual sulfur species at levels of 0.1–100 mg·kg⁻¹.

D-5623 does not purport to identify all individual sulfur components. Detector response to sulfur is linear and essentially equimolar for all sulfur compounds within the standard’s scope (1.1). Both unidentified and known individual compounds can be determined. Many sulfur compounds, for example, hydrogen sulfide and mercaptans, are reactive and their concentration in samples may change during sampling and analysis. Consequently, the total sulfur content of samples is estimated from the sum of the individual compounds determined. The D-5623 test method is not the preferred method for determination of total sulfur if some other less roundabout analysis method is available.

Other possible applicable standards for sulfur analysis are:

- ISO 4260 Petroleum Products and Hydrocarbons – Determination of Sulfur Content – Wickbold Combustion Method
- ASTM D-1219 – Fuel, Aviation Turbine, Mercaptan Sulfur in (Color Indicator Method)
- ASTM D-129 – Sulfur in Petroleum Products (General Bomb Method), Standard Test Method for
- ASTM D-1323 – Fuels, Aviation Turbine, Mercaptan Sulfur in, Amperometric and Potentiometric Methods
- ASTM D-2747 – Trace Quantities of Total Sulfur in Volatile Organic Liquids (Oxyhydrogen Combustion Method)
- ASTM D-2785 – Trace Quantities of Total Sulfur (Wickbold & Beckman Combustion Apparatus)

7.12 Detection and Measurement of Oxygenates in Fuel

Tests applicable to gasoline are not necessarily applicable to its blends with oxygenates. Consequently, the type of fuel under consideration must first be identified in order to select applicable tests. Standard D-4814 outlines the oxygenate requirements and Test Method D-4815 provides a procedure for determining oxygenate concentration in mass percent. These tests have not yet to withstand the test of time, so always exercise appropriate professional judgment in their use.

7.12.1 D4814-c Automotive Spark-ignition Engine Fuel

Though not really an analysis standard, D-4814 sets the guidelines in establishing requirements of automotive fuels for ground vehicles equipped with spark-ignition engines. It is included here as a reminder to analysts that this is the defining specification for the amounts and types of oxygenates that are required to be in RFG, including such items as seasonality and variations in amounts. It changes often and the latest version should always be used for setting control targets in the blender.

D-4814 describes various characteristics of automotive fuels for use over a wide range of operating conditions. It provides for a variation in the volatility and water tolerance of automotive fuel in accordance with seasonal climatic changes at the locality where the fuel is used. For the period May 1 through September 15, the maximum vapor pressure limits issued by the US EPA are specified for each geographical area except Alaska and Hawaii. Variation of AKI with seasonal climatic changes and altitude is discussed in Appendix X1 of D-4814. This specification neither necessarily includes all types of fuel that are satisfactory for automotive vehicles, nor necessarily excludes fuels that can perform unsatisfactorily under certain operating conditions or in certain equipment. The significance of each of the properties of this specification is shown in Appendix X1 of D-4814.

The spark-ignition engine fuels covered in this specification are gasoline and its blends with oxygenates such as alcohols and ethers. This specification does not apply to fuels that contain an oxygenate as the primary component, such as fuel methanol (M85). The concentrations and types of oxygenate are not specifically limited in this specification. However, depending on oxygenate type, as oxygenate content increases above some threshold level, the likelihood of vehicle problems also increases. The composition of both unleaded and leaded fuel is limited by economic, legal, and technical considerations, but their properties, including volatility, are defined by this specification. In addition, the composition of unleaded fuel is subject to the rules, regulations, and CAA waivers of the US EPA. With regard to fuel properties, including
volatility, this specification can be more or less restrictive than the US EPA rules, regulations, and waivers. Refer to Appendix X3 of the Standard for discussions of US EPA rules relating to fuel volatility, lead and phosphorous contents, and use of oxygenates in blends with unleaded gasoline. Contact US EPA for the latest versions of the rules and additional requirements.

D-4814 represents a description of automotive fuel as of the date of publication. The specification is under continuous review, which can result in revisions based on changes in fuel, automotive requirements, or test methods, or a combination thereof. All users of this specification, therefore, should refer to the latest edition.

7.12.2 D4815-a Determination of Methyl Tertiary Butyl Ether, Ethyl Tertiary Butyl Ether, Tertiary Amyl Methyl Ether, Diisopropyl Ether, Tertiary Amyl Alcohol and C5 to C7 Alcohols in Gasoline by Gas Chromatography

This test method is designed for the determination of ethers and alcohols in gasolines by GC. Specific compounds determined are: MTBE, ETBE, TAME, DIPE, methanol, ethanol, isopropanol, n-propanol, isobutanol, tert-butanol, sec-butanol, n-butanol, and tert-pentanol (tert-amylalcohol).

Individual ethers are determined from 0.1 to 20.0 mass%. Individual alcohols are determined from 0.1 to 12.0 mass%. Equations used to convert to mass percent oxygen and to volume percent of individual compounds are provided. Alcohol-based fuels such as M-85 and E85, MTBE product, ethanol product and denatured alcohol are specifically excluded from this method. The methanol content of M-85 fuel is considered beyond the operating range of the system.

Benzene, while detected, cannot be quantified using this test method, and must be analyzed by alternate methodology (Test Method D-3606 or D-4420).

Test Method D-4815 also includes procedures for calculating mass oxygen content and oxygenate concentration in volume percent. Appendix X4 of the method provides a procedure for calculating the mass oxygen content of a fuel using measured oxygenate type, oxygenate concentration in volume percent, and measured density or relative density of the fuel.

7.12.3 D5599 Determination of Oxygenates in Gasoline by Gas Chromatography and Oxygen Selective Flame Ionization Detection

This test method covers a GC procedure for the quantitative determination of organic oxygenated compounds in gasoline which have a FBP not greater than 220°C and oxygenates which have a bp limit of 130°C. It is applicable when oxygenates are present in the 0.1–20% by mass range.

D-5599 is intended to determine the mass concentration of each oxygenate compound present in a gasoline. This requires knowledge of the identity of each oxygenate being determined (for calibration purposes). However, the oxygen-selective detector used in this test method exhibits a response that is proportional to the mass of oxygen. It is, therefore, possible to determine the mass concentration of oxygen contributed by any oxygenate compound in the sample, whether or not it is identified. Total oxygen content in a gasoline may be determined from the summation of the accurately determined individual oxygenated compounds. The summed area of other, uncalibrated or unknown oxygenated compounds present, may be converted to a mass concentration of oxygen and summed with the oxygen concentration of the known oxygenated compounds.

7.12.4 D5622 Determination of Total Oxygen in Gasoline and Methanol Fuels by Reductive Pyrolysis

The test methods in this standard cover the quantitative determination of total oxygen in gasoline and methanol fuels by means of reductive pyrolysis methods. Precision data are provided for 1.0–5.0 mass% oxygen in gasoline and for 40–50 mass% oxygen in methanol fuels.

Several types of instrument can be satisfactory for these test methods. Instruments can differ in the way that the oxygen-containing species is detected and quantified. However, these test methods are similar in that the fuel is pyrolyzed in a carbon-rich environment.

7.13 Detection and Measurement of Nitrogen in Fuels

7.13.1 D5291 Instrumental Determination of Carbon, Hydrogen, and Nitrogen in Petroleum Products and Lubricants

D-5291 is a catch-all standard to cover the instrumental determination of carbon, hydrogen, and nitrogen in laboratory samples of petroleum products and lubricants. Values obtained represent the total carbon, the total hydrogen, and the total nitrogen.

These test methods are applicable to samples such as crude oils, fuel oils, additives, and residues for carbon, hydrogen and nitrogen analysis. These test methods were tested in the concentration range of at least 75–87 mass% for carbon, at least 9–16 mass% for hydrogen, and 0.1–2.0 mass% for nitrogen.

The nitrogen test method is not applicable to light materials or those containing <0.75 mass% nitrogen, such as hydrotreated gasoline, jet fuel, naphtha, diesel fuel, or chemical solvents. These test methods are not recommended for the analysis of volatile materials such as gasoline, gasoline–oxygenate blends, or gasoline-type aviation turbine fuels.
The results of these tests can be expressed as mass percent carbon, hydrogen or nitrogen.

Other standards of interest for fuels nitrogen analysis are:
- ISO 13379 Petroleum Products – Determination of Alkyl Nitrate in Diesel Fuels – Spectrometric Method
- ASTM D-3228 – Determination of Nitrogen by Kjeldahl Method
- ASTM D-4629 – Determination of Trace Nitrogen by X-ray Fluorescence

7.14 Detection and Measurement of Metals in Fuels

These tests are infrequently used in an era where no-lead is the preferred environment. There are instances, where native or contaminant crude-cut metal porphyrins, for example, need to be determined (they poison conversion catalysts). Appropriate test procedures are:
- ISO 6245 Petroleum Products – Determination of Ash
- ISO/FDIS 14597 Petroleum Products – Determination of Vanadium and Nickel Content – Wave-length-dispersive X-ray Fluorescence Spectrometry
- ASTM D-3231 – Determination of Phosphorus Content in Gasolines

7.15 Measurement of Fuel Densities

Although not directly a regulated quantity, the density of a petroleum stock is so important to the proper characterization of the stream that it at least needs to be mentioned. Units reported are degrees API or specific gravity. A relatively simple inspection property is given in:
- ASTM D-287 and D-1298 – Measure Density, Relative Density, or API Gravity of Crude Petroleum and Liquid Hydrocarbon Products

Output signals from certain coriolis-method flowmeters have a direct relationship between signal frequency and liquid density, but these methods are yet to be accepted as standards.

8 ON-LINE ANALYSES FOR REGULATORY CONTROL

8.1 General

Some of the techniques and standards mentioned in sections 6 and 7 are strictly for laboratory-based analyses only. The techniques are either complicated, potentially hazardous, or the machinery needed to perform the analysis is large and clumsy, not at all adaptable to online packaging and monitoring in a modern refinery. Two techniques, however, have shown themselves to be readily adaptable to such installations. These are the spectrophotometric analysis of fuel streams by multiple IR absorption with chemometric analytical techniques and the use of fast sample systems in conjunction with GC.

Other methods besides these have been put in online environments, UV absorption and even LC, but these two methods hold by far the greatest interest for gasoline blenders in terms both of accuracy of method and available equipment and the wide variety of the tests they can reliably and economically perform. Therefore, the following discussion will cover these methods in detail from the standpoint of their adoption to real-time on-line monitoring.

8.2 On-line Analysis for Blender Control – Chemometric Methods

This discussion is presented here, as it is critical to obtain accurate IR analytical results. IR is one of the most common of all on-line spectrophotometric methods, so the following is geared for use with on-line varieties of IR analysis, most particularly NIR methods. Other techniques for several different spectrophotometric analysis procedures beyond NIR are described previously in this work. The comments presented below are generally applicable to sample preparation and techniques for other spectrophotometric methods in general.

8.2.1 Near-infrared for On-line Gasoline Analysis – General

Near-infrared (NIR) analysis has a tremendous growth in usage for monitoring several process stream qualities of importance to gasoline blenders, in real-time. Although widespread use of NIR has been delayed by some technical challenges, refineries adapting this technology have had significant provable benefits from the installation. Significant savings derive from allowing optimal process configurations and conditions, using fewer instruments, and cost effectively measuring parameters specified by regulatory agencies.

NIR is a fast spectroscopic technique that can be put readily into industrial grade [i.e. able to withstand dust, splashing, vibration, noise, electromagnetic interference (EMI), temperature extremes – within reason] enclosures for on-line blending. NIR offers low cost per analysis in terms of time, equipment cost, and sample processing. With NIR, all analyses are completed in the time it takes to obtain a spectrum (about 1 min), regardless of how many properties are being analyzed. A single
NIR analyzer can replace multiple traditional analyzers, providing faster results. NIR can be used to monitor physical properties, such as gasoline octane number or diesel CN, or chemical properties such as the percentage of aromatics or saturates.

One of the main advantages of NIR analyzers is that they are compatible with conventional quartz fiber optics. With fiber optics, light can pass from the source to the fiber optic, then through the sample, before it is focused onto the detector. This separates the electronics of the analyzer from the sample, which is desirable, particularly when the sample is a combustible liquid. Despite the advantages of fiber optics, their use can cause difficulty for the analytical measurement. First, there is an economic incentive to place the fiber in the stream, blend header, or pipeline. If this can be done, the need for detailed sample conditioning is avoided and the cost of installing additional sample piping. A primary drawback to this strategy is that gasoline streams contain contaminants that may adversely affect the in-line probe.

Figure 13 shows a schematic plus open cabinet display of a Fourier transform NIR gasoline analyzer typical of those currently on the market.

8.2.2 Infrared Calibration – Model Validation

Calibration of an NIR analyzer requires a training set of samples for which the properties of interest have been measured by conventional methods. For many applications, a new calibration must be done for each refinery and, sometimes, for each instrument.

Traditional analytical techniques usually depend on a single variable. NIR, on the other hand, is an example of a chemometric technique. In chemometric techniques, the property to be determined, RVP, as a good example, depends on many variables, often in complex, highly nonlinear relationships that may not always be well known before calibration begins.

The process of NIR calibration begins with obtaining the NIR spectra of a training set of samples for which the properties of interest have been measured by traditional means. In the case of a set of gasoline samples, octane numbers would be measured by octane engines, RVP by Grabner cell analysis, and aromatics by laboratory FIA.

Models (equations) that relate the measured properties of the samples to their spectra are generated using a computer and statistical regression analysis or neural net software. These models allow prediction of the properties of unknown samples directly from their spectra. The model predictions are accurate, as long as the unknown samples are sufficiently similar to the training-set samples. Inaccurately predicted samples can be added to the training set to develop a revised model that has greater generality.

Model generality is less of a concern when predicting chemical composition than when predicting physical properties. This is because chemical composition is observed directly as peaks in a spectrum, whereas physical properties are inferred from a complicated correlation to their chemical composition. Generality is also less of a concern when modeling an individual process unit, such as a reformer, because the composition of the product does not vary as widely from day to day as do finished gasolines of several different grades.

Even when unknown samples are too different from the training set to permit accurate (true) predictions, NIR predictions can still be quite precise (repeatable). For those trying to control and optimize a process unit, the immediacy and precision of NIR predictions can be more important than their accuracy (where a bias can always be installed). This is particularly true when trying to determine the changes in process stream properties following a change in operating parameters.

8.2.3 Calibration – Temperature Effects

Temperature affects the analytical measurement because the amount of light absorbed by the sample is a function of the density of the material, and hydrocarbon densities change with temperature. Temperature can also affect the transmission characteristics of the fiber optic. One reason for this is that the fiber, like the sample, absorbs part of the light, and the magnitude of that absorption is a function of temperature. This is a major problem for in-stream placement of NIR sensors in that the temperature becomes as an uncontrolled variable introduced into the calibration model.

Ambient temperature is not an important factor in the transmission of digital signals by fiber optics. The user
should be aware, however, that NIR sources produce continuous light emissions in an analog fashion and that the magnitude of the output is important.

Partial compensation can be made for any of the temperature-induced inaccuracies, but the effects of temperature can greatly exceed the error of the analyzer. The variance of error so introduced by temperature is directly additive to the variance of the total system error. Therefore, like analyzer error, it must be controlled at least to the number of significant figures desired in the measured property.

8.2.4 Calibration – Reference Sampling

A final consideration that deserves attention is the type of reference scan made by the analyzer. An absorbance measurement involves the use of a reference sample to calculate a ratio. Systems that use a stored reference scan, or systems where the reference fiber optic does not experience the same environmental conditions as the sample fiber (length of fiber run, temperature changes, etc.) can add even more error to the absorbance measurement. Several refiners have historically used on-line NIR analysis successfully for conventional and ethanol-blended gasolines (a hot technical topic in the synfuel-oriented 1980s) in feedback closed-loop control. Most find that the use of a “protofuel” validation system is invaluable, especially when measuring multiple targets of gasoline blends. There are several ways to do this effectively.

For example, the system can be preset to run before, during, and near the end of the blending operation. If the calibration has changed, as indicated by the statistical analyses, a well-designed NIR system will correct the equations automatically and produce a printed report. This validates the on-line NIR analyzer according to ASTM D-3764.

Protofuels provide a high-quality assurance (QA). Under the best conditions, contaminants may deposit to some extent on the probe, the lamp sources may degrade slightly, and the instrument electronics or optical system may change over time. Validation with protofuels will alert a “smart” system and allow it automatically to correct if any of these factors start to have an effect.

For example, the system can be preset to run before, during, and near the end of the blending operation. Section 9.1 of this article covers sampling techniques from the viewpoint of the regulatory agencies.

8.2.5 Property Measurement Procedures – Sampling

The most common approach to component property measurement is to sample the component tank, measure the properties, and enter the values in a data table. This can take a day or more and occurs weekly or less in most plants. At least one refinery, however, samples and tests its component tanks daily.

A second less-common approach is to use results from the streams as they are released from the process units. These results are then averaged or filtered for use in blending. This process makes double use of unit analyzers or routine samples, but the tests frequently exclude important properties such as octane.

If done less often than daily, the tank-sampling method assumes that component properties are reasonably steady over several days. Both approaches assume tanks are well mixed. Unfortunately, these assumptions frequently are invalid. Component tanks are often active and usually stratified. An active tank is one into which current production goes at the same time as the blend component is drawn off. Tank stratification typically results from a minimal physical size of the tanks and the common practice of putting inlet and outlet nozzles near each other.

Properties of real components vary constantly. This variability comes from feed changes, unit upsets, day-to-night temperature swings affecting overhead condensers, and the thousand natural shocks to which units are subject.

The reason these assumptions are used is that realistic assumptions do not yield a useful calculation method. Most refiners, therefore, have decided that it is better to have useful numbers based on poor assumptions than no numbers.

8.2.6 Property Measurement Procedures – On-line Measurement

The on-line measurement of component properties has long been recognized as desirable, but up to the late 1980s the costs made it impractical for most refiners. The most important property traditionally was octane, the measurement of which with on-line knock engines is slow and capital- and labor-intensive. This provided the original impetus to install on-line control in order to reduce expensive “octane giveaway”.

The other most critical economic qualities, RVP and distillation, were less expensive to measure on-line, but the payback for these was not as worthwhile either, until the advent of regulatory controls. US EPA Phase I and more certainly Phase II and CARB regulations have completely turned the economics of blending upside down. Now the primary factor is to minimize “RVP giveaway” and maximize the amount of heavier naphtha, while still meeting T90 specifications. An octane-barrel is no longer worth what it used to be and is now on last priority after the environmental regulations. While this is the way it should be for a serious “smog-fighting” environment, it is also one of the many reasons why reformulated fuels cost more than their petroleum-derived ancestors.
NIR equations often “split hairs” to distinguish between similar-looking spectra. This high sensitivity to subtle differences between spectra means that NIR regression equations can also be sensitive to subtle differences in instrument response. Any instrument instabilities, such as slight drifts or jumps in an NIR instrument’s response, can result in unacceptable deviations in the NIR predictions.

Similarly, if there is even a small difference in response between two instruments, the NIR equation developed on the first instrument will probably not work on the second without modification (i.e. calibration transfer), even if both instruments are the same make and model. Some instrument vendors claim to have resolved the calibration transfer issue in their software or hardware. Others just limit their guarantees to certain systems and ranges of composition. Just as is the case with model generality, the simpler analysis applications are less affected by the issues of instrument stability and calibration transfer.

8.3 On-line Analysis for Blender Control – Gas Chromatography Methods

In order to satisfy a refinery’s quality and regulatory control requirements, on-line analysis of several parameters are required. Perhaps the most versatile methodology for this is GC. Much time and effort has gone into this methodology for measurement of several parameters that it is necessary to know with regard to gasoline blends. The results generally show good correlation between the analyzers and the more traditional laboratory analysis methods mentioned previously in this article.

Trends in blending call for specialized gas chromatographs in gasoline and diesel blending for such qualities as \( V/L \) (vapor liquid ratio), correlated RVP, and simulated distillation correlation of ASTM D-2887 or D3710 to ASTM D-86. The correlation provided by the GC analyzer’s manufacturer is tuned against laboratory results to provide continuous monitoring and evaluation for control and maintenance of “on-spec” blends. This improved control reduces component giveaway based on the analyzer’s repeatability and accuracy. The readings from the such analyzers are consistently within 0.1–0.2 psi (0.7 to 1.38 kPa) for most gasoline grades, premium, midgrade, and regular unleaded gasoline.

With the new, more effective RVP analyzers in place, and with the addition of the octane engine and simulated distillation analyzers, gasoline properties, including octane measurements, RVP, distillation, and vapor-over-liquid ratio, can also be closed-loop controlled. As a result, gasoline blending now can be implemented with multivariable/optimization controls to capture additional benefits.

Other GC analyzers have been used with varying success in optimization of blend characteristics such as total aromatics, total sulfur, and oxygenates and benzenes to measure octane ratings.

8.3.1 Discrete Component Analyses

The GC/PIANO (paraffins, isoparaffins, aromatics, napthenes, olefins) technique is the primary test method used for the determination of benzene, aromatics, and olefins contents of the blended gasolines. The method incorporates state-of-the-art, high-resolution GC.

The sample is injected into a capillary column, which is temperature-programmed, then separated into its components (possibly 400 or more compounds.) The data-acquisition system and software integrate the area under each peak and normalize the data, after adjusting for detector response factors for each compound. Each peak is then grouped into one of the five Piano hydrocarbon types. Finally, a detailed list of the hydrocarbon groups and each component, in weight percent and volume percent, is produced.

8.3.2 Evaluating Distillation Using Gas Chromatography-simulated Distillation Methods

To meet the strict environmental and performance specifications of US EPA/CARB-type gasolines in blend operations, while maintaining or even improving profit margins, accurate determination of the distillation assay is essential. Refiners use D86 T50 and T90 values to set blend run operating parameters and check results. Although it is possible to determine D86 through physical distillation in the laboratory, these methods are time-consuming. One analysis can take from 2 to 6h. In addition, physical distillation methods require at several milliliters of the product. Although it has been tried in various refining environments, on-line distillation analyzers are clumsy, difficult to maintain and calibrate, and often inaccurate. Simulated distillation provides accurate information on blend components and can be packaged in a manner conducive to continuous real-time analysis. Simulated distillations are GC determinations of the bp range of the components in a sample mixture. ASTM D-86 is the method to which most if not all gasoline is sold. While ASTM D-86 is not the only laboratory distillation method, it is the most common, since it is the easiest to perform.

Two ASTM methods, D-2887 and D-3710, described standardized GC to perform a simulated distillation assay. GC simulated distillation methods offer better distillation results and accurate information on the boiling range distribution. They also offer several operational advantages over physical ASTM methods for D86 and D1160 in the laboratory. Unless the analyst using laboratory-based...
physical distillation methods follows the ASTM procedures rigorously and his or her equipment meets the test standards, the test results are too often inconsistent.

It is possible to compare the results of the various methods for determining distillation curves. ASTM method D-2892 obtains TBP results using a laboratory distillation unit with 15 theoretical plates. Simulated distillation results closely match the results obtained from ASTM D-2892. Simulated distillation and ASTM D-86 also give similar results for bps less than 400 °C.

8.3.3 On-line Reid Vapor Pressure Analysis

US EPA Phase I and II regulatory compliance needs, along with the addition of oxygenates and other local regulatory requirements, have redefined gasoline blending rules and left refineries vulnerable to millions of dollars in additional cost. Precise on-line analyzer measurement and closed-loop control of key gasoline specifications, such as RVP, are critical to efficient cost-effective blending under these circumstances.

Accurate and repeatable RVP measurements allow more low-value stocks (such as butane) to be used in the blending, without switching to more expensive blending components. Butanes are readily available, economical, and increase fuel vapor pressure as well as octane. Typically, every 0.1 psi closer to the targeted blend RVP value represents an annual saving of up to $400 000 based on 50 000 BBI/day blended.

Blended gasoline specifications must be measured either in the laboratory or on-line, where process analyzers play a key role. While other refinery processes can be closed-loop controlled using inferential methods, gasoline blending closed-loop control relies totally upon on-line analyzers. Therefore, both analyzer accuracy and reliability are critical in order to control RVP successfully with a closed-loop.

Historically, blenders used continuous mechanical (Hallikainen-type) RVP analyzers. These required intensive maintenance because of their moving parts and, despite modifications to operating procedures, and preventative maintenance, their accuracy and reliability of analytical service was still poor. The modifications included shutting down analyzers when not in use and allowing analyzers from each header to service the others when necessary in order to increase reliability.

There were significant differences between analyzer readings and laboratory results for the gasoline grab samples. There was a bias adjustment for each of the old analyzers, but because of the differences in readings, the technician had to change the bias constantly, making the closed-loop RVP control scheme difficult at best.

The on-line time of the mechanical RVP closed-loop controls was poor, usually below 50%. Because of the uncertainty of the on-line analyzer readings, the rate of RVP giveaway was typically and uneconomically high. Several GC-based analyzers and a few vapor pressure flow-cell analyzers went on the market with the necessary characteristics. A quality on-line RVP analyzer will have the following key qualifications:

1. Its repeatability is 0.005 psi and its reproducibility is 0.15 psi vs an accuracy of 0.3 psi for the old analyzer. Inferential predictive methods are no better than this either.
2. It stays on stream, with little or no maintenance.
3. Its cycle time is less than 20 min.
4. It does not require special calibration beyond standard GC methodology.
5. It incorporates up-to-date microprocessor-based technology.

The RVP controllers will typically take the analyzer signals and adjust butane or light straight run naphtha rates to meet RVP targets or set points. To ensure smooth continuous control, inferential dead-time compensated controllers should be used to treat the discrete RVP analyzer signal. The controllers are carefully tuned based on the analyzer cycle time, the response of the fast sample loop, and the system dynamic.

Because the cycle time of the RVP analyzer is about 8–20 min, the response of the RVP controller is adequate to handle most blending disturbances. Typically, the controller can control RVP within 0.1–0.2 psi (0.7 to 1.38 kPa) of the set point, as illustrated in the above graphs. The newer RVP analyzers also provide a safety check to detect analyzer failure. This is done by hardwiring the analyzer trouble alarm directly to the distributed control system (DCS). It replaces the jump check and the stagnant check to detect bad RVP signals.

Since these GC-based RVP analyzers have been installed in refineries, they have usually performed reliably. Typical problems include such incidences as leaking valves and fittings, loss of air supply to the analyzers, and so on. Required repairs after startup infancy troubles are minimal compared to the previous mechanical systems. Analyzer repeatability is good. In order continually to prove the accuracy of the analyzers, high-purity but readily and economically available reference components such as 2,3-dimethylbutane (RVP 7.8 psi) and 2,2-dimethylbutane (RVP 9.8 psi), and normal pentane (RVP 15.4 psi) should occasionally be used to check analyzer repeatability and reproducibility. Also a Graebner RVP analyzer is used to check against on-line RVP results. This is an important check because most regulatory agencies certify or require certification of results with Graebner-type analyzer measurements on the grab samples.
9 MAINTAINING QUALITY CONTROL OF ON-LINE ANALYSES

9.1 Blend Certification Sampling and Testing Procedures

Samples that accurately represent batch properties are necessary in order to determine if regulatory standards are being met. Several book references and standards describe how to do sampling properly so a general treatise on this topic will not be pursued here. It is useful, however, to consider how the regulatory agencies prefer to specify testing procedures.

CARB regulations state\(^\text{77}\) that “each refiner or importer shall determine the value of each of the [RFG] properties for each batch of RFG it produces or imports prior to the gasoline leaving the refinery or import facility, by collecting and analyzing a representative sample of gasoline taken from the batch.” “Batch of reformulated gasoline” is defined at as “a quantity of reformulated gasoline which is homogeneous with regard to those properties which are specified for reformulated gasoline certification.” Therefore, the first concern of batch sampling is to determine whether or not the tank contents are homogeneous.

Gravity analyses of upper, middle, and lower samples are a suggested means of establishing tank homogeneity. US EPA would consider a tank to be homogeneous where the maximum difference in tested gravities between any two samples from different tank strata is no greater than 0.6 API, unless there is reason to believe the tank contents are not mixed in spite of such gravity test results. For example, if samples from a storage tank have noticeably different colors, the gasoline in the tank should not be considered homogeneous even if the samples have gravity tests that are within the 0.6 API range. If a question remains about whether the contents of a storage tank are fully mixed following gravity testing, the party could resolve the homogeneity issue by conducting tests on the upper, middle and lower tank samples for benzene and oxygen. Tank homogeneity could be established using benzene and oxygen tests on upper, middle and lower tank samples without the need for gravity testing. The US EPA would consider a tank to be homogeneous if the maximum difference in benzene tests is 0.10 vol% and the maximum difference in oxygen tests is 0.15 wt%. The benzene and oxygen testing to establish homogeneity (as opposed to certification testing) could use a nonregulatory method such as mid-IR analysis.

In cases where the tank contents are not homogeneous, further in-tank or reblend mixing should be performed before collecting a representative sample for RFG analysis. Product stratification should also be avoided downstream of refiner or importer facilities, because samples must meet the downstream “per gallon” standards, and stratification could result in a portion of the gasoline in a tank being out of compliance with “per gallon” standards.

The US EPA mandates that storage tanks should be sampled\(^\text{78}\) using the method that will best represent the contents of the tank or batch. The refiner, importer, or independent laboratory should use its best professional judgment in determining the procedures that are necessary in order best to represent a given batch within the guidelines of its Appendix D, which contains general instructions and precautions that must be followed when choosing sampling equipment and containers, and when collecting samples.

US EPA preference for sampling storage tanks is a “running” or “all-levels” sample collected from an unconfined (no gage tube) roof port. A “running” or “all levels” sample collected from a perforated gage tube is the next best choice. In no case should a sample be collected from a solid gage tube.

US EPA prefers to collect “running” samples as opposed to “all-levels” samples for two reasons. First, assuming that both “all-levels” and “running” samples are collected with uniform lowering and retrieval rates, the “running” procedure achieves better representation of the tank contents than the “all-levels” procedure. This occurs because with the “running” procedure, one half of the sample is collected when lowering the apparatus, and the column sampled is undisturbed at that point. The second reason is that “running” samples are easier to collect than “all-levels” samples because the sample collector is not required to stopper the sample bottle.

If a tank cannot be bottle sampled from the top, then tap sampling is an appropriate substitute. For best representation, a single composite should be collected by proportionally filling the sample container from all available taps. If homogeneity is well documented, the entire sample may be collected from a single tap. If a refinery or importer tank has no roof sampling port or sampling taps, then a pipeline sample is the only other sampling means that is possible.

CARB inspectors obtain gasoline samples using the sampling procedure in section 2296, Motor Fuel Sampling Procedures. Generally, “running samples” or “all-levels samples” will be obtained from refinery and terminal tanks that have appropriate access from a sample hatch. “Tap samples” will be obtained from those tanks that do not have hatches. “Nozzle samples” will be obtained from service station nozzles. As to how many samples will be obtained, the CARB inspectors generally obtains two samples, one to be used for RVP analysis and the other for all the other fuel analysis.

In the case of downstream QA sampling from a storage tank which does not have a roof sampling port or taps for
sampling, a sample collected from a truck or barge that has just loaded from that tank is marginally acceptable. The truck or barge should be completely empty before loading, and a “running” sample should be collected from the truck or barge compartment.

RVP is the most sensitive RFG property, relative to sampling, and therefore precautions to prevent loss of “light ends” must be followed carefully. Also, sampling containers must be clean and rinsed well with the gasoline to be sampled, so that the sample is not contaminated, for example, with trace amounts of heavy metals. When collecting tap samples, the tap and connecting piping must be completely flushed, and the sample container must be bottom-filled strictly according to the procedure outlined in Appendix D or section 2296 depending upon the collection locality. In all cases, the sampler should label the container as soon as possible and note the location of the sampling point and method of collection. This may save several headaches at a later time if there are any questions about the measurement value or methodology.

As far as generally acceptable practices for in-line or “pipeline” samplings go, ASTM D-4177, Standard Practice for Automatic Sampling of Petroleum and Petroleum Products is probably the most applicable guidance for sampling methodology. This practice covers information for the design, installation, testing, and operation of automated equipment for the extraction of representative samples of petroleum and petroleum products from a flowing stream and storing them in a sample receiver. If sampling is for the precise determination of volatility, use Practice D5842 in conjunction with this practice. For sample mixing, refer to Practice D5854. Petroleum products covered in this practice are considered to be a single phase and exhibit Newtonian characteristics at the point of sampling.

D4177 is applicable to petroleum and petroleum products with vapor pressures at sampling and storage temperatures less than or equal to 101 kPa (14.7 psi). Refer to D5842 when sampling for RVP determination. Petroleum products whose vapor pressure at sampling and sample storage condition is above 101 kPa (14.7 psi), and liquefied gases [that is, liquid natural gas (LNG), liquefied petroleum gas (LPG) etc.], are not covered by this practice.

While the procedures covered by this practice will produce a representative sample of the flowing liquid into the sample receiver, specialized sample handling may be necessary to maintain sample integrity of more volatile materials at high temperatures or extended residence time in the receiver. Such handling requirements and procedures for sampling these fluids are described in Practice D1265, Test Method D1145, and Gas Processors’ Association (GPA) 2166.

Annex A2 of 4177 contains theoretical calculations for selecting the sampler location. Annex A3 lists acceptance methodologies for sampling systems and components. Annex A4 gives performance criteria for permanent installations, while Annex A5 has the criteria for portable sampling units. Appendix X1 is a design data sheet for automatic sampling systems; Appendix X2 compares the percent sediment and water to unloading time period.

Other applicable standards for sampling and measurement set-up are:

- API-DR-214 – Sampling and Analytical Methods for Determining Petroleum Hydrocarbons in Gasoline
- API-MPMS-C13-S1 – Chapter 13 – Statistical Aspects of Measuring and Sampling, Section 1
- API-MPMS-C13-S2 – Chapter 13 – Statistical Aspects of Measuring and Sampling, Section 2
- ISO 3170 Petroleum Liquids – Manual Sampling
- ISO 3171 Petroleum Liquids – Automatic Pipeline Sampling

9.2 Infrared Analysis Preparation(73,79)

9.2.1 Chemometric Calibrations

Chemometric calibration techniques require substantial amounts of data for many calibrations. If this calibration data contains unknown or uncontrolled sample and spectrometer variations, the calibration requires more data with all of these variations included. Such a result may not be robust since it becomes specific, not only to the stream being measured, but also to the specific spectrometer and to the other uncontrolled variations in the system. A better calibration method is to reduce or eliminate as many sources of noise as possible. Reducing sources of variation makes the calibration simpler and more robust. The calibration models can benefit from good sample conditioning and the use of stable, properly functioning spectroscopic hardware. This fact is often overlooked at the chemometric calibration stage because techniques such as partial least squares regression (PLS) can “fit” noise. This does not mean, however, that the calibration models can predict noise, or deal with “new” noise. (50)

Systematic noise such as temperature variation or spectrometer wavelength drift can be partially modeled away by including the temperature variation or wavelength shifting in the calibration set. However, this greatly increases the size and cost of the calibration dataset.
Further, compensating for system noise in this way adds variation into the calibration dataset unrelated to the analyte. This noise in the data can mask and degrade the information of interest in spectrum, and ultimately make the analysis impossible. These issues will be discussed in detail below.

The preferred philosophy is to control as many potential sources of sample-related variations as possible. This means controlling sample, temperature, pressure, flow, particulate, and undesired phases. The sample system is used to facilitate automated true referencing and zeroing of the spectrometer. Also required is the use of a robust and well-designed spectroscopic analyzer that minimizes errors in the data due to wavelength shifts, spectral distortions, stray light, light intensity changes, or nonlinearities.

9.2.2 Sample Filtering

Sample filtering can also be crucial to quality spectroscopy. Particulate in the sample will cause scattering in the spectrum that may lead to curved, nonreproducible spectral backgrounds. A typical means of removing particulates is via centrifugal type filters with a 5–10 μm filter element. An emulsion such as water in a hydrocarbon can cause spectral scattering. This water scattering is particularly prevalent in hydrocarbons in the second and third NIR overtone regions (800–2000 nm). Water can be removed with a centrifugal-type filter. Because water is so insoluble in hydrocarbons, even a few hundred parts per million can cause scattering.

Another use for a sample system is to remove bubbles in the sample. As long as bubbles separate easily from the sample, they can be removed simply by stopping sample flow in the sample cell and allowing the bubbles to float to the top of the cell. Stop flow can also be used to eliminate the possibility of turbulent flow in the sample cell that can cause scattering due to density gradients. Turbulent flow is particularly likely in cells or probes with a path length greater than 1 mm.

It is important in sample system design that the system itself does not create bubbles. In a high volatility sample like gasoline, bubbles can be formed by a pressure drop in the system itself. Therefore flow and low-pressure control valves should be located after the sample cell. Bubbles can also be eliminated by assuring that liquid sample flow is up into the cell. This takes advantage of gravity, so that if a bubble is formed it will flow harmlessly up and out of the cell.

9.2.3 Spectrometer Maintenance

A well-designed fluid switching system can be advantageously used to maintain and monitor optical system and spectrometer performance. This allows reference fluids, protofuels, and wash solvents, as well as dry air or nitrogen to be switched into the sample cell. These functions will be required in a pending ASTM method for validation of NIR spectroscopic analyzers using chemometric-based calibrations.

Most process spectrometers designed for monitoring liquids and gases are “single beam” instruments. If a second reference path exists, the reference path is seldom the same as the sample path. The raw single beam spectrum obtained contains information about the sample in the sample cell and the wavelength-dependent response of the spectrometer and sample cell. To remove the effect of the spectrometer response, a spectrometer reference spectrum is required. The spectrum is ratioed against the single beam spectrum to give a spectrometer-independent spectrum. This reference spectrum is ideally a spectrum taken through the empty sample cell. It can be expected that this reference spectrum will change with time. Some changes that can affect the reference include contamination of the sample cell or ageing of the spectrometer light source. On a typical, well-stabilized spectrometer a new reference spectrum is generally recommended once every 8–24 h. This time may vary depending on the sample and the sensitivity of the calibration equations to cell contamination. Obtaining such a new reference is straightforward with a fluid switching system in place and can be an automated scheduled event that requires no manual intervention.

Obtaining a reference spectrum is accompanied by a cell wash cycle to remove sample buildup on the sample cell windows.

A typical wash and reference sequence for an on-line gasoline spectrometer follows:

1. Flush cell with toluene wash solvent – sending the toluene to the process, a flare line, or hydrocarbon waste sewer
2. Flush with pentane – other solvents may be used as long as they are volatile
3. Reverse flow through cell to top-to-bottom
4. Flush with dry nitrogen or air
5. Take the reference spectrum
6. Run diagnostics on the spectrum – if they pass, use the spectrum as the new reference, if not, alarm and keep old reference
7. Return to analysis mode.

If the spectroscopic analyzer does not have a sample system, then the sample cell or probe must be removed to be cleaned or for a reference spectrum to be obtained. Other approaches using a second optical path, such as a short-fiber loop or a dual optical path probe, exist for obtaining a reference spectrum. These approaches are all limited in that they do not take into account all the changes in the system. In particular they miss possible contamination of the sample cell or cell windows.
Depending on the configuration there are usually other assumptions as well, such as assuming that two optically different optical paths have the identical effect on the spectrum.

9.2.4 Spectrometer and Property Calibration Diagnostics
A sample system allows diagnostics of the spectrometer system itself and the property calibration equations. Such diagnostics as cell cleanliness, detector linearity, light source intensity, optical alignment, signal-to-noise, stability, and optical purging quality can all be determined automatically when a reference is taken. These tests assure that the results will be of high quality.

A sample system also allows introduction of a calibration material into the sample cell. A pure compound can be used for wavelength and cell path length checks. A measure of the overall system performance can be obtained by introducing a known sample such as a proto-fuel and checking the PLS prediction results.

A typical calibration cycle would be as follows:
1. execute reference cycle
2. introduce calibration fluid
3. acquire spectrum
4. run diagnostics, archive results, alarm if indicated
5. return to analysis.

9.2.5 Extractive Sampling
For gases and low-viscosity liquids, an extractive sample system provides a better quality spectroscopic analysis. An extractive system assures spectral quality and reproducibility and a clean thermostatted sample. An extractive system allows for cost-effective sample multiplexing and automated system diagnostics. Perhaps the feature that is most important to the analysis is that such a system requires minimal manual maintenance.

Extractive sampling allows the use of an optically simple transmission cell. Pure transmission sampling is the preferred method for calibrations because of its high degree of reproducibility from cell to cell. Such a cell typically has windows sufficiently large so as not to shade off the beam. Any sample spectrum distortion due to the cell is minimized. This is crucial to eliminate the adjustment of the PLS calibrations if a cell is replaced or disassembled for cleaning. If transmission sampling is used it is possible for a technician to replace a cell without any adjustments or impact on the calibration.

Extractive sampling is a cost-effective means of sample multiplexing as compared with optical multiplexing. The use of optical multiplexing does not eliminate the need for sample conditioning. Instead, it requires multiple distributed sample conditioning systems. Multiplexing of 1–3 sample streams is common with extractive systems, and many more are possible.

There are cases where extractive sampling is not possible. This may be due to safety, sample viscosity, or very fast cycle time. If so, the preferred approach is a local extractive sample system with a fiber-optic flow-through cell. This will provide all of the sample control of other extractive systems. The use of fiber optics introduces new optical elements into the system. The characteristics of the fiber probe, optical multiplexer, fiber and fiber–spectrometer interface must be carefully controlled to assure spectral reproducibility.

9.3 Calibration and Acceptance Testing of Gas Chromatography/Simulated Distillation Analyzers for D86/Reid Vapor Pressure Analysis
Careful calibration of on-line analyzers is absolutely essential to the success of real-time fuels blending control. Performance of factory and in-field acceptance testing is a critical part of any such analyzer installation.

As part of in-field or factory acceptance tests (FAT) it is not unusual for GC/simulated distillation analyzers to behave inconsistently and show excessive deviation from laboratory data [as much as 100–150°F (38–66°C)]. Consequently, such analyzers are often shipped back to the manufacturer, corrected, and their performance verified using additional samples supplied by the refinery laboratory. These samples included all the sample types projected for analysis on these analyzers. Owing to time limitations, not all samples may be run on every analyzer but sufficient data was collected to be confident that the analyzers will be able to perform the required analyses with the expected precision.

Two common problems often arise in gasoline analyzer configuration. A presplitter or stabilizer flash cell may need to be added to each analyzer to prevent overloading the (typically FID) detector with samples containing high C5 concentrations. Flow sensor placement may also present problems. Typically such sensors should be placed on the outlet side of the sample valve unless pressure relief line or cabinet space requirements dictate otherwise. Inlet flow detectors are often a source of cross-contamination of successive samples.

Acceptance criteria for the correlated D-86 data should be based upon the reproducibility of the D-86 method [15°F/8.3°C for initial boiling point (IBP), 19°F/10.5°C for FBP and 7–12°F/3.9–6.7°C for 10–90% distillation points]. Acceptance for computed RVP numbers is usually 0.2 psi.

Once the factory test has been validated to the proper standard, initial biases of the data can be established. Biases are a set of analyzer offsets that allow the correlation of the analyzer data with laboratory data at each reported distillation and RVP data point. These
Table 14 Typical results for test samples analyzed by GC at acceptance tests

</table>

are utilized in normal on-line analyzer operation to improve the accuracy of the analyzer data (relative to laboratory values). During normal operations, these factors should occasionally (3–6 months) be revalidated as a part of normal quality assurance (QA) standards work.

Table 14 shows an initial field acceptance test result matrix for three analyzers which failed QA standards. They were returned to the manufacturer for rework and a subsequent retest at the manufacturer’s location. (80)

Tables 15 through 17 show the comparison of laboratory results with the GC analyzer distillation and RVP results for the second QA test samples. Also compiled are analyzer computed V/L20 data which were included in the analyzer specification as output data but were not measured by the refinery laboratory. These data, as well as the Table 14 data, are shown without any bias offsets of the data, since the statistical analysis must be done on the actual data taken by the instrument. The precision of the GC analyzer data, as measured by the SDs, is better than the precision of the laboratory data for both the distillation points and the RVP results. The pooled standard deviation for the distillation points (averaged over all equipment, samples and distillation points) was 1.1 °F/0.6 °C for the GC analyzers and 3.2 °F/1.8 °C for the laboratory distillation analyzers. For RVP, the pooled SD for the GC analyzers was 0.05 psi compared to 0.22 psi for the laboratory data. Agreement between the GC analyzer data and the laboratory distillation data was acceptable, with a few peculiar exceptions. The 10% and 20% points on the regular gasoline sample were low by 18 °F/10 °C and 13 °F/7.2 °C, respectively. In the front end of the hydrocrackate sample, the IBP was 28 °F/15.6 °C high while the 10–30% points were low. The IBP for the reformate sample was 58 °F/32.2 °C high. Of most concern was the hydrocrackate data, which showed a minimum value in the temperature vs volume% curve around 20% distilled. This appears to be due to the high C5 content of the sample, which (according to the GC data) comprises about 40% of the sample. For RVP, agreement between the GC data and laboratory data was acceptable, with the exception of the hydrocrackate sample (probably, also due to the high C5 content) and, marginally, the regular blend sample (0.23 psi difference probably due to the low front-end distillation points).

Fortunately, for the hydrocrackate and reformate samples (those samples with the most serious discrepancy between GC and laboratory), analytical data was

SD, standard deviation. Prior data for the regular gasoline was not available to test the efficacy of the correction on that sample. However, the same deviations in distillation points and RVP were not observed in the regular initial test sample. The selection of bias corrections will represent a compromise over the range of compositions typical for a particular product or blend stock, and more data will have to be collected to determine the appropriate offsets for the regular gasoline product. Acceptable agreement could be obtained for the regular gasolines by averaging the offsets for the two regular gasolines. Nevertheless, the deviations observed in the uncorrected regular blend data could not be attributed to analyzer error.

With these results, the distillation analyzers were judged to be performing with sufficient accuracy and precision to justify acceptance of the units.

Available for samples collected from those units over a period of time spanning about one month. This allowed a measurement of the applicability of the biases to correct the difference between the laboratory and GC data. For these samples, the bias estimations and the resulting corrected data are shown in Table 18. Here, biases are computed from the first test samples and are applied to the retest samples. These corrections produced acceptable data for all the distillation points and RVP. It was particularly encouraging that the initial test and retest hydrocrackate samples had different bp curves and vapor pressures (indicating some change in sample composition over that period) but the bias corrections were applicable in the face of the composition change. For each sample, sets of biases will need to be determined in the field and periodically checked.

**10 REFORMULATED FUELS ANALYSIS GLOSSARY**

**10.1 Introduction**

This glossary is intended to help interested citizens understand the most commonly used air pollution terms. The glossary is divided into three sections:

1. governmental section: these terms apply to the USA unless stated otherwise
2. technical section
3. standards and associations.

**10.1.1 Governmental Section**

APCD (Air Pollution Control District): a county agency with authority to regulate stationary, indirect, and area sources of air pollution (e.g. power plants, highway construction, and housing developments) within a given county, and governed by a district air pollution control board composed of the elected county officials (compare AQMD).

AQMD (Air Quality Management District): a group of counties or portions of counties, or an individual county specified in law with authority to regulate stationary, indirect, and area sources of air pollution within the region and governed by a regional air pollution control board comprised mostly of elected officials from within the region (compare APCD).

Attainment area: a geographic area which is in compliance with the national and/or California Ambient Air Quality Standards (see NAAQSs or CAAQSs).

BACT (Best Available Control Technology): the most up-to-date methods, systems, techniques, and production processes available to achieve the greatest feasible emission reductions for given regulated air pollutants and processes. BACT is a requirement of NSR (New Source Review) and PSD (Prevention of Significant Deterioration).

</table>
CAAAQS (California Ambient Air Quality Standard): a legal limit that specifies the maximum level and time of exposure in the outside air for a given air pollutant and which is protective of human health and public welfare (Health and Safety Code 39606b). CAAQSs are recommended by the California Office of Environmental Health Hazard Assessment and adopted into regulation by the Air Resources Board. CAAQSs are the standards which must be met per the requirements of the California Clean Air Act (CCAA).

CARB (California Air Resources Board): the state’s lead air quality agency consisting of a nine-member Governor-appointed board. It is responsible for attainment and maintenance of the state and federal air quality standards, and is fully responsible for motor vehicle pollution control. It oversees county and regional air pollution management programs.

CCAA (California Clean Air Act): a California law passed in 1988 which provides the basis for air quality planning and regulation independent of federal regulations. A major element of the Act is the requirement that local APCD/AQMDs in violation of the CAAQS must prepare attainment plans which identify air quality problems, causes, trends, and actions to be taken to attain and maintain California’s air quality standards by the earliest practicable date.

Emission Offset (also known as an emission trade-off): a rule-making concept whereby approval of a new or modified stationary source of air pollution is conditional on the reduction of emissions from other existing stationary sources of air pollution. These reductions are required in addition to reductions required by BACT.

Emission Standard: the maximum amount of a pollutant that is allowed to be discharged from a pollutant source such as an automobile or smoke stack.

FCAA (Federal Clean Air Act): a federal law passed in 1970 and amended in 1977 and 1990 which forms the basis for the national air pollution control effort. Basic elements of the act include NAAQSs for major air pollutants, air toxics standards, acid rain control measures, and enforcement provisions.

FIP (Federal Implementation Plan): in the absence of an approved State Implementation Plan (SIP), a plan prepared by the US EPA which provides measures that non-attainment areas must take to meet the requirements of the FCAA.

NAAQS (National Ambient Air Quality Standards): standards set by the federal US EPA for the maximum levels of air pollutants which can exist in the outdoor air without unacceptable effects on human health or the public welfare.

Non-attainment Area: a geographic area identified by the US EPA and/or CARB as not meeting either NAAQS or CAAQS standards for a given pollutant.

PSD (Prevention of Significant Deterioration): a program used in development of permits for new or modified industrial facilities in an area that is already in attainment. The intent is to prevent an attainment area from becoming a nonattainment area. This program, like NSR, can require BACT and, if an CAAQS is projected to be exceeded, emission offsets.

SIP (State Implementation Plan): a document prepared by each state describing existing air quality conditions and measures which will be taken to attain and maintain NAAQSs (see AQMD).

TAC (Toxic Air Contaminant): an air pollutant, identified in regulation by the CARB, which may cause or contribute to an increase in deaths or in serious illness, or which may pose a present or potential hazard to human health. TACs are considered under a different regulatory process (California Health and Safety Code section 39650 et seq.) than pollutants subject to CAAQSs. Health effects to TACs may occur at extremely low levels, and it is typically difficult to identify levels of exposure which do not produce adverse health effects.

US EPA (United States Environmental Protection Agency): the United States agency charged with setting policy and guidelines, and carrying out legal mandates for the protection of national interests in environmental resources.

10.1.2 Technical Section-I, General

AAQS (Ambient Air Quality Standards): health and welfare based standards for clean outdoor air which identify the maximum acceptable average concentrations of air pollutants during a specified period of time (see CAAQS and NAAQS in the section 10.1.1, and Criteria Air Pollutant below).

Acute Health Effect: an adverse health effect which occurs over a relatively short period of time (e.g. minutes or hours).

Aerosol: particles of solid or liquid matter that can remain suspended in air for long periods of time because of extremely small size and lightweight.

Air Pollutants: amounts of foreign and/or natural substances occurring in the atmosphere that may result in adverse effects on humans, animals, vegetation, and/or materials.

Air Quality Simulation Model: a mathematical relationship between emissions and air quality which simulates the transport, dispersion, and transformation of compounds emitted to the air.

Air Toxics: a generic term referring to a harmful chemical or group of chemicals in the air. Typically, substances that are especially harmful to health, such as those considered under US EPA’s hazardous air pollutant (HAP) program or California’s Assembly Bill 1807 TAC program, are considered to be air toxics. Technically, any compound...
that is in the air and has the potential to produce adverse health effects is an air toxic.

**Alternative Fuels**: fuels such as methanol, ethanol, natural gas, and liquid propane gas that are cleaner burning and help to meet CARB’s mobile and stationary emission standards.

**Ambient Air**: the air occurring at a particular time and place outside of structures. Often used interchangeably with outdoor air.

**BACT (Best Available Control Technology)**: the most up-to-date methods, systems, techniques, and production processes available to achieve the greatest feasible emission reductions for given regulated air pollutants and processes. BACT is a requirement of NSR and PSD.

**Chronic Health Effect**: an adverse health effect which occurs over a relatively long period of time (e.g. months or years).

**Criteria Air Pollutant**: an air pollutant for which acceptable levels of exposure can be determined and for which an ambient air quality standard has been set. Examples include ozone, carbon monoxide, nitrogen dioxide, sulfur dioxide, and PM-10 (Particulate Matter) (see individual pollutant definitions).

**Emission Inventory**: an estimate of the amount of pollutants emitted from mobile and stationary sources into the atmosphere over a specific period such as a day or a year.

**Hazardous Air Pollutant (HAP)**: an air pollutant considered by US EPA to be particularly hazardous to health. Emission sources of HAPs are identified by US EPA, and emission standards are set accordingly.

**Hydrocarbon**: any of a large number of compounds containing various combinations of hydrogen and carbon atoms. They may be emitted into the air as a result of fossil fuel combustion, fuel volatilization, and solvent use, and are a major contributor to smog (also see ROG (Reactive Organic Gas)).

**Inversion**: a layer of warm air in the atmosphere that lies over a layer of cooler air, trapping pollutants.

**Mobile Sources**: sources of air pollution such as automobiles, motorcycles, trucks, off-road vehicles, boats, and airplanes (contrast with stationary sources).

**Nitrogen Oxides** (oxides of nitrogen, NOₓ): a general term pertaining to compounds of nitric oxide (NO), nitrogen dioxide (NO₂), and other oxides of nitrogen. Nitrogen oxides are typically created during combustion processes, and are major contributors to smog formation and acid deposition. NOₓ is a criteria air pollutant, and may result in numerous adverse health effects.

**Ozone**: a strong smelling, pale blue, reactive toxic chemical gas consisting of three oxygen atoms. It is a product of the photochemical process involving the sun’s energy. Ozone exists in the upper atmosphere ozone layer as well as at the earth’s surface. Ozone at the earth’s surface causes numerous adverse health effects and is a criteria air pollutant. It is a major component of smog.

**Ozone Precursors**: chemicals such as hydrocarbons and oxides of nitrogen, occurring either naturally or as a result of human activities, which contribute to the formation of ozone, a major component of smog.

**Photochemical Reaction**: a term referring to chemical reactions brought about by the light energy of the sun. The reaction of nitrogen oxides with oxygen in the presence of sunlight to form ozone is an example of a photochemical reaction.

**PM-10 (Particulate Matter)**: a major air pollutant consisting of tiny solid or liquid particles of soot, dust, smoke, fumes, and mists. The size of the particles (10µm or smaller, about 0.0004 inches or less) allows them to enter the air sacs deep in the lungs easily, where they may be deposited and result in adverse health effects. PM-10 also causes visibility reduction and is a criteria air pollutant.

**Pollutant Standards Index (PSI)**: a numerical index used for reporting severity of air pollution. The higher the index, the higher the level of pollutants and the greater likelihood of health effects.

**Pollution Prevention**: the use of materials, processes, or practices to reduce, minimize, or eliminate the creation of pollutants or wastes. It includes practices that reduce the use of toxic or hazardous materials, energy, water, and/or other resources.

**Risk Assessment**: an evaluation of risk which estimates the relationship between exposure to a harmful substance and the likelihood that harm will result from that exposure. Risk assessments are generally expressed as the estimated chance per million that a person, exposed over some period of time (e.g. a 70-year lifetime) and some specified concentration of exposure, will experience a certain effect.

**ROG (Reactive Organic Gas)**: a reactive chemical gas, composed of hydrocarbons, that may contribute to the formation of smog. Also sometimes referred to as nonmethane organic compounds (NMOCs).

**Sensitive Groups**: identifiable subsets of the general population that are at greater risk than the general population to the toxic effects of a specific air pollutant (e.g. infants, asthmatics, elderly).

**Smog**: a combination of smoke, ozone, hydrocarbons, nitrogen oxides, and other chemically reactive compounds which, under certain conditions of weather and sunlight, may result in a murky brown haze that causes adverse health effects. The primary source of smog in California is motor vehicles.

**SO₂ (Sulfur Dioxide)**: a strong smelling, colorless gas that is formed by the combustion of fossil fuels. Power plants, which may use coal or oil high in sulfur content, can be major sources of SO₂, SO₃ and other sulfur oxides.
contribute to the problem of acid deposition. SO\textsubscript{2} is a criteria pollutant.

**Vapor Recovery Systems**: mechanical systems that collect and recover chemical vapors resulting from transfer of gasoline from operations such as tank-to-truck systems at refineries, tanker-to-pipeline systems at offshore oil operations, and pump-to-vehicle systems at gasoline stations.

**VOCs (Volatile Organic Compounds)**: hydrocarbon compounds which exist in the ambient air. VOCs contribute to the formation of smog and/or may themselves be toxic. VOCs often have an odor, and some examples include gasoline, alcohol, and the solvents used in paints.

10.1.3 Technical Section – II

**Additive**: any material added to a base stock to change its properties, characteristics or performance.

**Aniline Point**: the lowest temperature at which equal volumes of aniline and hydrocarbon fuel or lubricant base stock are completely miscible. A measure of the aromatic content of a hydrocarbon blend, used to predict the solvency of a base stock or the CN of a distillate fuel.

**Antistatic Additive**: an additive that increases the conductivity of a hydrocarbon fuel to hasten the dissipation of electrostatic charges during high-speed dispensing, thereby reducing the fire/explosion hazard.

**Base Stock**: the base blending material, usually a straight run or refined naphtha fraction, into which additives are blended to produce finished gasolines.

**Carbon Residue**: coked material remaining after an oil has been exposed to high temperatures under controlled conditions.

**Catalytic Converter**: an integral part of vehicle emission control systems since 1975. Oxidizing converters remove hydrocarbons and carbon monoxide (CO) from exhaust gases, while reducing converters control nitrogen oxide (NO\textsubscript{x}) emissions. Both use noble metal (platinum, palladium or rhodium) catalysts that can be “poisoned” by lead compounds in the fuel or lubricant.

**Cetane Index**: a value calculated from the physical properties of a diesel fuel to predict its CN.

**Cetane Number (CN)**: a measure of the ignition quality of a diesel fuel, as determined in a standard single cylinder test engine, which measures ignition delay compared to primary reference fuels. The higher the CN, the easier a high-speed, direct-injection engine will start, and the less white smoking and diesel knock after start-up.

**Cetane Number Improver**: an additive (usually an organic nitrate) that boosts the CN of a fuel.

**Cloud Point**: the temperature at which a cloud of wax crystals appears when a lubricant or distillate fuel is cooled under standard conditions. Indicates the tendency of the material to plug filters or small orifices under cold weather conditions.

**Compression Ratio**: in an IC engine, the ratio of the volume of combustion space at bottom dead center to that at top dead center.

**Copper Strip Corrosion**: a qualitative measure of the tendency of a petroleum product to corrode pure copper.

**Density**: mass per unit volume.

**Detergent**: a substance added to a fuel or lubricant to keep engine parts clean. In motor oil formulations, the most commonly used detergents are metallic soaps with a reserve of basicity to neutralize acids formed during combustion.

**Detergent/Dispersant**: an additive package that combines a detergent with a dispersant.

**Detonation**: uncontrolled burning of the last portion (end gas) of the air/fuel mixture in the cylinder of a spark-ignition engine. Also known as “knock” or “ping”.

**Distillation**: the basic test used to characterize the volatility of a gasoline or distillate fuel. For gasoline testing, ASTM D-86 is the defining standard procedure for use.

**Emissions (Mobile Sources)**: the combustion of fuel leads to the emission of exhaust gases that may be regarded as pollutants. Water and CO\textsubscript{2} are not included in this category, but CO, NO\textsubscript{x} and hydrocarbons are subject to legislative control. All three are emitted by gasoline engines; diesel engines also emit particulates that are controlled.

**End Point**: highest vapor temperature recorded during a distillation test of a petroleum stock.

**Exhaust Gas Recirculation (EGR)**: system to reduce automotive emission of nitrogen oxides (NO\textsubscript{x}). It routes exhaust gases into the carburetor or intake manifold, where they dilute the air/fuel mixture and reduce peak combustion temperatures, thereby reducing the tendency for NO\textsubscript{x} to form.

**Flash Point**: minimum temperature at which a fluid will support instantaneous combustion (a flash) but before it will burn continuously (fire point). Flash point is an important indicator of the fire and explosion hazards associated with a petroleum product.

**Gasohol Blend**: a spark-ignition automotive engine fuel containing methanol or denatured fuel ethanol in a base gasoline. It may be leaded or unleaded.

**Gasoline**: a volatile mixture of liquid hydrocarbons, containing small amounts of additives and suitable for use as a fuel in spark-ignition IC engines.

**Gravity**: in petroleum products, the mass/volume relationship expressed as Equations (6) and (7):

$$
\text{specific gravity} = \frac{\text{mass/unit volume product at 60}^\circ\text{F (15}^\circ\text{C})}{\text{mass/unit volume water at 60}^\circ\text{F (15}^\circ\text{C})}
$$

(6)
Hydrofinishing: a process for treating raw extracted base stocks with hydrogen to saturate them for improved stability.

Induction Period: in an oxidation test, the time period during which oxidation proceeds at a constant and relatively low rate. It ends at the point where oxidation rate increases sharply.

Inhibitor: additive that improves the performance of a petroleum product by controlling undesirable chemical reactions, i.e. oxidation inhibitor, rust inhibitor, and so on.

Insolubles: contaminants found in used oils due to dust, dirt, wear particles or oxidation products. Often measured as pentane or benzene insolubles to reflect insoluble character.

Lead: commonly used name for tetraethyl or tetramethyl lead, an additive used in gasoline to improve octane ratings. Elemental lead is commonly used in sleeve bearing and bushing alloys.

Naphthenic: a type of petroleum fluid derived from naphthenic crude oil, containing a high proportion of closed-ring methylene groups.

Octane Number: a measure of a fuel's ability to prevent detonation in a spark ignition engine. Measured in a standard single-cylinder, variable-compression-ratio engine by comparison with primary reference fuels. Under mild conditions, the engine measures research octane number (RON); under severe conditions (MON). Where the law requires posting of octane numbers on dispensing pumps, the AKI is used. This is the arithmetic average of RON and MON, (R + M)/2. It approximates the road octave number, which is a measure of how an average car responds to the fuel.

Octane Requirement (OR): the lowest octane number reference fuel that will allow an engine to run knock-free under standard conditions of service. Octane requirement is a characteristic of each individual vehicle.

Octane Requirement Increase (ORI): as deposits accumulate in the combustion chamber, the octane requirement index of an engine increases, usually reaching an equilibrium value after 10000–30000 km. Octane requirement index is a measure of the increase, which may be in the range of three to ten numbers.

Oxidation: occurs when oxygen attacks petroleum fluids. The process is accelerated by heat, light, metal catalysts and the presence of water, acids, or solid contaminants. It leads to increased viscosity and deposit formation.

Oxidation Inhibitor: substance added in small quantities to a petroleum product to increase its oxidation resistance, thereby lengthening its service or storage life; also called antioxidant.

Oxidation Stability: resistance of a petroleum product to oxidation and, therefore, a measure of its potential service or storage life.

Oxygent: an oxygen-containing ashless organic compound, such as alcohol or ether, that can be used as a fuel or fuel supplement.

Oxygented Fuels: fuels for IC engines that contain oxygen combined in the molecule, e.g. alcohols, ethers and esters. Term also applies to blends of gasoline with oxygenates, e.g. gasohol, which contains 10% by volume anhydrous ethanol in unleaded gasoline.

Ozone and CO Nonattainment Areas: any area of the continental USA that does not meet the 1990 CAA requirements for carbon monoxide or ground-level ozone pollutants.

Paraffinic: a type of petroleum fluid derived from paraffinic crude oil and containing a high proportion of straight chain saturated hydrocarbons. Often susceptible to cold flow problems.

Positive Crankcase Ventilation (PCV): system for removing blow-by gases from the crankcase and returning them through the carburetor intake manifold to the combustion chamber where the recirculated hydrocarbons are burned. A positive crankcase valve controls the flow of gases from the crankcase to reduce hydrocarbon emissions.

Pour Point: an indicator of the ability of an oil or distillate fuel to flow at cold operating temperatures. It is the lowest temperature at which the fluid will flow when cooled under prescribed conditions.

Pour Point Depressant: additive used to lower the pour point or low-temperature fluidity of a petroleum product.

Preignition: ignition of the fuel/air mixture in a gasoline engine before the spark plug fires. Often caused by incandescent fuel or lubricant deposits in the combustion chamber, it wastes power and may damage the engine.

Refining: series of processes to convert crude oil and its fractions into finished petroleum products, including thermal cracking, catalytic cracking, polymerization, alkylaion, reforming, hydrocracking, hydroforming, hydrogenation, hydrogen treating, hyrofining, solvent extraction, dewaxing, de-oiling, acid treating, clay filtration and de-asphalting.

Rerefining: a process of reclaiming used lubricant oils and restoring them to a condition similar to that of virgin stocks by filtration, clay adsorption or more elaborate methods.

Syncrude: unconventional crudes such as those derived from tar sands, oil shale and coal liquefaction.

US EPA Complex Model: implemented on January 1, 1997. The model is more restrictive than the simple model, and contains limits on RVP, oxygen, olefins, benzene,
sulfur, and T-90. In addition, it includes requirements on aromatic content and T-50 temperatures, added in 1998. **US EPA Oxygenated Gasoline**: required annually from September 15 to March 15 for use in most CO nonattainment areas. Oxygenated gasoline is defined as a spark-ignition engine fuel meeting ASTM D-4814 specifications and blended to include a minimum of 2.0% mass oxygen and a maximum of 1.0% volume benzene. **US EPA Simple Model**: used to define RFG. Effective January 1, 1995. The model includes RVP and oxygen content requirements to reduce volatile organic compound emissions. It caps oxygen, benzene, sulfur, olefins, and T-90 content at levels equal to or lower than a refiner’s 1990 baseline. **Vapor Pressure, Reid (RVP)**: measure of the pressure of vapor accumulated above a sample of gasoline or other volatile fuel in a standard bomb at 100 °F (37.8 °C). Used to predict the vapor locking tendencies of the fuel in a vehicle’s fuel system. Controlled by law in some areas to limit air pollution from hydrocarbon evaporation while dispensing.

Crude oil at the wellhead is a hot, high pressure fluid that contains gases, oil, water vapor and solid impurities. This mixture is processed in a gas oil separator where it is brought to atmospheric pressure and separated into gases, water, solid and stabilized oil. Characterization of a stabilized crude oil is carried out using a number of analytical methods for both its physical and chemical properties. These methods include use of a densitometer for density measurement and a hydrometer for specific gravity and American Petroleum Institute (API) gravity. The densitometer provides more precise and reproducible measurement of density as well as better control of the temperature of the sample. Pour point is determined using a cooling and pouring method, water content determination by distillation, ash content by a high temperature burning method, while salt content of a crude is determined by an electrometric method. The metal contents are determined using inductively coupled plasma atomic emission spectrometry (ICPAES) and atomic absorption spectrometry (AAS). The ICPAES is faster as compared to AAS and provides simultaneous determination of a wide range of metals. The elemental analysis is carried out by oxidative combustion of the sample in which carbon, hydrogen and sulfur are measured in oxide form, while nitrogen is measured in the form of molecular nitrogen. Sulfur is also determined using atomic emission spectrometry (AES) and chemiluminescent detectors which are very sensitive as compared to the oxidative combustion method. In addition, chemiluminescent detectors also provide nitrogen determination. Molecular weight is determined using thermoelectric measurement of vapor pressure; however the values obtained are influenced by the temperature of the measurement and the type of solvent used for dissolving the sample. Gel permeation chromatography (GPC) is used for average molecular weight determination of crude oil. Physical distillation is used for producing light and middle distillates and residue fractions based on the desired boiling range or volume percent range of a crude oil as well as determination of the boiling range distribution. Gas chromatography (GC) is utilized for determination of boiling range distribution by simulated distillation, volatile compound determination and identification of crude oil spill. The faster analysis time, better reproducibility and equivalent results are some of the advantages of simulated distillation over physical distillation in the determination of the boiling range distribution of a crude oil. Gas chromatography/mass spectrometry (GC/MS) separates and identifies volatiles and low boiling components of a crude oil while mass spectrometry (MS) is utilized for assessing the molecular weights of the compounds. High-performance liquid chromatography (HPLC) is used for separation and quantification of hydrocarbon group types such as saturates, aromatics and polars. Aromatics are further separated into monoaromatics, diaromatics, triaromatics and polyaromatics. Liquid chromatography (LC) is used to fractionate the whole crude oil into desired fractions such as acids, bases and neutral nitrogen compounds. Petroleum resins are separated from whole crude oil by a liquid chromatographic method using ion-exchange resins. Liquid chromatography/mass spectrometry (LC/MS) provides separation and
positive identification of high boiling compounds of a crude oil. Supercritical fluid chromatography (SFC) is used for separation and identification of hydrocarbon group types. Compared to HPLC, SFC provides better separation of high boiling components. Infrared (IR) spectroscopy is used for determination of type of functional group and hydrogen bonding, thermal analysis for evaluating the thermal stability of the crude oils and classification of hydrocarbons while titrimetry is used for determining acid number, base number and water content.

1 INTRODUCTION

Crude oil or full range crude is a complex mixture of hydrocarbons and heteroatomic hydrocarbons which range from the simple one-carbon atom compound, methane, to highly condensed aromatics to metallic constituents such as porphyrins and asphaltenes. Crude oil at the wellhead is characterized by a hot, high velocity mixture of oil, water, hydrocarbon and nonhydrocarbon gases along with salts and sand. This mixture is then stabilized to remove gases, solids and water from oil which is a viscous brown to black liquid. The main groups of compounds present in the stabilized crude oils are: normal or straight chain alkanes (paraffins); branched alkanes (isoparaffins); cycloalkanes (naphthenes); aromatics; sulfur, nitrogen and oxygen containing compounds; and compounds having metals such as vanadium, nickel and iron. Due to this complexity, various analytical approaches are used to characterize crude oils. The characterization of the crude oil is performed either as a whole or after separating into a number of fractions based on boiling range or compound types. Analytical methods applied to whole crude oil provide information about its physical and chemical properties as well as the presence of relative amounts of different petroleum products.

2 HISTORY

The history of analytical methods starts with the discovery of crude oil. Early characterization techniques were very crude and provide limited information about the properties and composition of crude oil. These techniques and methods were more of manual type and slow and incorporated a wide variety of human errors. These methods were capable of providing only information regarding the light ends of the crude oil. The detection limit of these methods was also quite high and could not determine the trace quantities of metals and heteroatoms such as sulfur, nitrogen and oxygen present in crude oil. With the passage of time, the analytical methods became more automated and the speed and reliability of these methods are now quite high. With the introduction of high temperature methods, it became possible to identify and characterize heavy crude and residue more efficiently. Today, the analytical methods applied to crude oils are highly automated and sophisticated and provide information regarding its physical and chemical properties in a faster and more reliable manner along with very high reproducibility and repeatability.

3 TERMINOLOGY

Alkanes, also known as paraffins, are saturated compounds of carbon and hydrogen having the general formula \( \text{C}_n\text{H}_{2n+2} \). Alkanes can be straight chain or branched.

Alkenes, also known as olefins, are unsaturated compounds of carbon and hydrogen having the general formula \( \text{C}_n\text{H}_{2n} \). Alkanes can be straight chain or branched.

API gravity, defined by API, \( \text{deg} = \frac{141.5}{\text{specific gravity}} - 35.5 \).

ASTM distillation, an American Society for Testing and Materials standard laboratory batch distillation process used for determining boiling range distribution of naphtha and middle distillate carried out at atmospheric pressure.

Atmospheric residue, residue left in the true boiling point (TBP) distillation of a crude oil carried out according to ASTM D-2892.

Bottom of the barrel, the high boiling residue obtained by distillation of a crude oil.

Carbon residue, the residue formed by evaporation and thermal degradation of a carbon containing material such as crude oil or petroleum residue.

Stabilized crude oil, also known as petroleum, whole crude oil or full range crude or stabilized crude oil, is a naturally occurring liquid hydrocarbon mixture having some gaseous components and may also contain compounds of sulfur, nitrogen, oxygen, metals as well as other elements.

Cut, also called fraction, is a portion of a crude oil having a certain boiling temperature limit.

DTA, differential thermal analysis, is a technique of measuring the amount of heat evolved or absorbed as a function of temperature at which these changes take place within the material. The temperature difference between a test sample and reference material is measured as a function of temperature, while the substance and the reference material are subjected to a controlled temperature heating.

DTG, differential thermogravimetry, is a technique of measuring the amount of material loss as a function of temperature at which these changes take place within
the material. The loss of the material between a test sample and reference material is measured as a function of temperature, while the substance and the reference material are subjected to a controlled temperature heating.

**FBP**, final boiling point at which 99.5% of the material is evaporated.

**Gas oil**, a petroleum distillate product heavier than kerosene. When produced from a TBP distillation process it is atmospheric gas oil (AGO), with an approximate boiling range 190–325 °C, and from vacuum distillation it is vacuum gas oil (VGO), with an approximate boiling range 299–500 °C.

**IBP**, initial boiling point at which 0.5% of the material is evaporated.

**Kerosene**, distillate fraction which boils in the range 150–300 °C.

**Light ends**, low boiling hydrocarbons present in a crude oil which are mainly methane to pentane.

**MBP**, the temperature at which one half of the material is evaporated.

**Middle distillate**, distillate fraction which boils in the range 150–370 °C.

**Naphtha**, the distillate which boils in the range 36–200 °C.

**Naphthenes**, also called cycloalkanes and cyclopafins, are cyclic compounds of carbon and hydrogen having single C–C bonds.

**Sour crude**, crude oil containing sulfur greater than 0.5–1.0 wt% percent or which contains a minimum of 0.05 cu ft of hydrogen sulfide per 100 gal of crude.

**Vacuum residue**, material left undistilled in the vacuum distillation of an atmospheric residue carried out according to ASTM D-1160.

4 COMPOSITION

#### 4.1 Wellhead Crude Oil

Crude oil wellhead streams are usually characterized as turbulent, high temperature, high velocity mixtures of gases, oil, water vapor and solid impurities. As these streams reach the surface, they undergo continuous reduction in temperature and pressure forming a two-phase flow: gas and liquid. These streams need to be processed to separate gas and oil as well as other solid impurities present, because they are very difficult to handle, meter, characterize or transport. These streams are fed to a gas oil separator where the pressure is successively decreased in several steps and brought to atmosphere pressure. At the gas oil separator, the streams are separated into natural gas, crude oil, water and solid. These phases are then separated and analyzed for the assessment of the wellhead stream composition. The composition of the wellhead crude oil depends upon the type of reservoir and the composition of wellhead natural gas. It contains a substantial amount of hydrocarbon gases. As the pressure is reduced, these gases are released from the oil and the crude is stabilized. A typical composition of a wellhead crude oil is given in Table 1 showing the type of components and their percentage.

Natural gas at the wellhead is normally associated with the oil. It may be in the form of free gas (gas not in solution) present at the top of the reservoir or dissolved in the oil (gas in solution) and its composition depends upon the type of reservoir. It is a complex mixture of hydrocarbons, mainly methane, ethane, propane and butane gases and some heavy hydrocarbons. Among these, methane and ethane are the most abundant.

#### 4.2 Stabilized Crude Oils

Petroleum or whole crude oil is a viscous brown to black liquid mixture. The main constituents of crude oils are hydrocarbons mixed with varying amounts of heteroatomic hydrocarbon compounds. All hydrocarbon classes except alkenes are practically present in crude oils. Alkanes, cycloalkanes, mono- and polynuclear aromatics are present in crude oils. The ratio of these classes, however, differs appreciably from one crude to another. Light hydrocarbon gases such as methane and ethane may be present in small amounts dissolved in the crude or in large amounts as in associated gas. Associated gas mainly constitutes methane, ethane and propane. This gas is a valuable raw material for many petrochemicals. In addition to the hydrocarbon mixture, crude oils contain variable amounts of heteroatomic hydrocarbon compounds such as sulfur, nitrogen and oxygen compounds. These compounds, sometimes referred to as impurities, affect the ways of processing the crude as well as its market value. A refiner would prefer

to process a low-sulfur crude since this will reduce the cost of hydrogen required for hydrotreatment of the products. Crude oils also contain trace amounts of heavy metals in the form of organometallic compounds and some inorganic salts, mainly sodium chloride. Some of these heavy metals, such as vanadium and nickel, are poisonous to processing catalysts. Crude oils having a high salt content are desalted before refining to reduce corrosion problems. The averaged elemental composition of stabilized crude oils is shown in Table 2. The compounds found in crude oils are given in Table 3 and generally belong to the following broad classes.

4.2.1 Hydrocarbons

The major constituents of most crude oils are hydrocarbon compounds besides minor concentrations of heteroatomic hydrocarbons. These hydrocarbon compounds are made up of hydrogen and carbon and belong to alkanes, cycloalkanes and aromatics. Alkanes, also known as paraffins, are saturated compounds having the general formula \( \text{C}_n\text{H}_{2n+2} \). The simplest hydrocarbon compound, methane, may be present in small amounts dissolved in the crude oil. Alkanes are both straight chain as well as branched types. Branched hydrocarbons in the naphtha range are more valuable as gasoline constituents compared to the straight chain isomers since they have higher octane number. Branched hydrocarbons have lower boiling points as compared to the straight chain isomers. Cycloalkanes, also called cycloparaffins or naphthenes, are normally present in crude oils in variable proportions. Cyclohexane, substituted cyclohexanes and substituted cyclopentanes are found in the naphtha fractions. Cycloalkanes are relatively more stable than alkanes. Aromatic compounds are normally present in all crude oils regardless of their type. However, \( \text{C}_6-\text{C}_8 \) mononuclear aromatics which are present in naphtha have commercial importance. These include benzene, toluene, xylenes and ethylbenzenes. The simplest aromatic compound, benzene (\( \text{C}_6\text{H}_6 \)), is one of the basic raw materials for petrochemical production. Aromatics in this range are not only important petrochemical feedstocks but are also valuable motor fuels. Polynuclear aromatic compounds are present in heavier petroleum fractions and residues. Asphaltene that are concentrated in heavy fuel oils and asphalt are polynuclear aromatics of a complex structure. It is known that condensed-ring aromatic hydrocarbons and heterocyclic compounds are the major constituents of asphaltenes.

4.2.2 Heteroatomic Hydrocarbons

Many types of heteroatomic hydrocarbon compounds occur in crude oils. The most important are sulfur, nitrogen and oxygen compounds. Metals are also present in trace amounts, mainly in the form of organometallic compounds such as vanadium and nickel porphyrins. Sulfur present in crude oils is mainly in the form of nonacidic organosulfur compounds. Sulfur compounds present in crude oil include mercaptans, sulfides, disulfides, thiophenes, benzo thiophenes and dibenzo thiophenes. Sour crudes contain a high percentage of hydrogen sulfide which is acidic in nature. However, many of the organosulfur compounds are not thermally stable and hydrogen sulfide is produced during crude processing. High-sulfur crude oils are less valuable since they require an additional cost for the removal of sulfur compounds. During hydrotreatment of petroleum products, hydrodesulfurization (HDS) takes place and the sulfur present in the heteroatomic compounds is converted into hydrogen sulfide. Naphtha fed to catalytic reformers is hydrotreated to reduce sulfur compounds to ppm levels to ensure a long life-cycle for the expensive reforming catalysts. Nitrogen compounds present in crude oils are usually low in
concentration and range from simple compounds such as pyridine and pyrrole to more complex structures such as porphyrins. The complex structures of porphyrins are usually found in heavy fuel oils and residues. Nitrogen compounds are basic, neutral and acidic types. These compounds are thermally more stable than the sulfur compounds. During hydrotreatment of petroleum products, hydrodenitrogenation (HDN) takes place and the nitrogen present in the heteroatomic compounds is converted into ammonia. Oxygen compounds in crude oils are more complex than sulfur compounds. Most oxygen compounds are weakly acidic, such as phenol, cresylic acid and naphthenic acids. The total oxygen content of many crude oils is very low. Nonacidic compounds such as esters, ketones and amides are less abundant than acidic compounds. Many of these oxygen compounds, however, are concentrated in the heavier portion of the crude. Many metals are found in crude oils; some of the more abundant are sodium, calcium, magnesium, aluminum, iron, vanadium and nickel. These normally occur in the form of inorganic salts such as sodium chloride, or in the form of organometallic compounds such as vanadium and nickel porphyrins, or in the form of salts of carboxylic acids, as in the case of calcium and magnesium. The organometallic compounds are usually concentrated in the heavier fractions and in crude oil residues.

5 CHARACTERIZATION METHODS

The whole crude or full range crude can be analyzed by a number of analytical methods. These analytical methods have been standardized by a number of societies and organizations such as ASTM, Institute of Petroleum (IP) and API. Among them, the ASTM provides a more comprehensive coverage of the analytical methods used for physical and chemical analysis of crude oils. Table 4 shows a summarized list of standard analytical methods used for the characterization of a crude oil. Figure 1 illustrates the variety of analytical techniques which are applied to characterize crude oils. Table 5 shows some of the properties of Arab Heavy and Alamein crude oils.

5.1 Physical Methods

5.1.1 Density, Specific Gravity and American Petroleum Institute Gravity

The density, specific gravity and API gravity is a rough measure of the quality of a liquid product. A high value of density or specific gravity and a lower value of API gravity would normally mean a heavy crude oil containing a lower percentage of the valuable light and middle fractions and a higher percentage of residue.

The density of a crude oil is the mass to volume ratio and is usually expressed in grams per milliliter (g ml\(^{-1}\)). The density of a crude is measured by a number of methods. These include the hydrometer method\(^{(1)}\) in which the crude oil sample is adjusted for its temperature and then poured into a cylinder.
The appropriate density range hydrometer is lowered into the sample and allowed to settle until temperature equilibrium is reached. Then, the hydrometer scale is read and the temperature of the sample is recorded. Temperature equilibrium is achieved quickly by putting the cylinder in a constant temperature bath. Another method specifies a standard test procedure for density and relative density measurement of crude oils by digital densitometer. In this method, a crude oil sample is introduced into an oscillating sample tube and the change in oscillating frequency with respect to change in mass of the tube is measured. The density of the sample is determined by comparing the measured sample response with the calibration data produced using a standard liquid sample. Specific gravity is measured directly using the ASTM D-1298 method utilizing the API hydrometer as the basis of determination.

5.1.3 **Salt Content**

There is a great variation in the salt content of crude oils depending mainly on the oilfield source, and possibly on the producing wells or zones within a field. The determination of the salt content of crude oil requires careful sampling. Salt content, expressed as sodium chloride, indicates the amount of salt dissolved in water. Salt content of a crude oil is determined electrometrically and is based on the conductivity of the crude oil solution. In this method, the sample is dissolved in a mixed polar solvent and then subjected to an alternating electrical stress. The flow of current is measured and the salt content is determined by comparing with a calibration curve of current versus salt content for a number of standard mixtures.

5.1.4 **Ash Content**

The ash content of a crude oil is an indication of metals and salts present as well as dirt and rust. The ash is usually in the form of metal oxides, stable salts and silicon oxides. The ash content is determined by burning a weighed quantity of whole crude oil sample contained in a high temperature resistant container in an atmosphere of air until the residue consisting of ash and carbon remains. The residue left is reduced by heating at 775 °C in a muffle furnace, then cooled and weighed.

5.1.5 **Carbon Residue**

Carbon residue is a rough indication of the asphaltic compounds and the materials that do not evaporate under conditions of the test, such as metals and silicon oxides. Carbon residue is the residue left after coking and cracking reactions occur during heating of the sample. Conradson carbon residue is determined by subjecting a sample of crude oil to destructive distillation in a crucible for a specified time period under a heating program. Ramsbottom carbon residue is obtained by quick heating of the crude oil sample contained in a glass bulb to 550 °C for a specified time period. Both of these methods provide a variable amount of carbon residue for a given sample. A correlation has been developed by the ASTM which shows that the difference between the two results decreases with increasing the amount of carbon residue in the sample.

5.1.6 **Molecular Weight**

Molecular weight is determined using a number of methods that include GPC, ultracentrifugation, electron microscope studies and MS. One of the most frequently used methods is the thermolectric measurement of vapor pressure of a series of solutions of crude oil
in an appropriate solvent. This method is also known as vapor pressure osmometry (VPO). A number of solutions having different concentrations of crude oil are prepared in pure solvent to measure their response. Generally, the solvents used for dissolution should be stable at the temperature of measurement and should not react with the crude oil sample. Some of the solvents frequently used are benzene, toluene, chloroform and 1,1,1-trichloroethane. Prior to proceeding with the crude oil solutions, a calibration curve is developed using a number of standard solutions of benzil in the same solvent in which the sample is dissolved. This calibration curve is used to determine the molecular weight of the crude oil.\(^{10}\) The value of the molecular weight from VPO must be weighed carefully because the measured value of molecular weight is a function of temperature and the molecular properties of the solvent. Higher dissolution of the crude oil is generally achieved in polar solvents, which leads to dissociation of the molecules and therefore results in low values of molecular weight. On the contrary, nonpolar or less polar solvents allow association of the molecules and therefore high molecular weights are obtained. Another method used for average molecular weight determination is GPC in which the whole crude oil sample is dissolved in an appropriate solvent. Some of the solvents which give best results in terms of solvency and suppression of interfering sorption effects are chloroform and benzene each containing 5% methanol. Other solvents such as trichlorobenzene, pyridine and methylnaphthalene are also used. The solution is filtered and introduced into the column where separation is achieved by the increasing size of the molecules and a plot of elution volume versus detector response is obtained. By comparing the elution volume of a standard sample with an unknown whole crude oil chromatographed under the same conditions, the average molecular weight is determined.\(^{11}\)

5.1.7 Water Content

Another standard method that utilizes a physical distillation technique is the determination of water present in the crude oil.\(^ {12}\) In this method, a known amount of crude oil sample is mixed with a suitable water-immiscible solvent such as methanol and heated under reflux to boiling. The water is condensed in a graduated trap and measured.

5.2 Extraction, Filtration and Centrifuging Methods

5.2.1 Sediment Content

The sediment present in a crude oil is important for the refining as well as trading point of view. The amount of sediment is determined by extracting with a hot organic solvent in a refractory thimble.\(^ {13}\) Sediment is also determined by the membrane filtration method. In this method, the sample is dissolved in hot toluene and filtered under vacuum through a 0.45-µm porosity membrane filter. The filter with residue is washed, dried and weighed to obtained the amount of sediment present in the sample.\(^ {14}\)

5.2.2 Asphaltene Content

Asphaltenes present in a crude oil are also separated using an \(n\)-alkane precipitation/extraction method in which crude oil sample is dissolved in an \(n\)-alkane solvent such as \(n\)-hexane, and the mixture is stirred for an hour at ambient temperature for dissolution. The \(n\)-alkane solvent acts as a precipitating agent and the choice of the solvent ranges from \(n\)-pentane to \(n\)-decane. In this process, the asphaltenes are precipitated. The resulting mixture is centrifuged at 2000 rpm to separate \(n\)-alkane-insoluble materials from the soluble portion of the crude oil. Then the solvent containing the soluble portion of the crude oil is decanted. To the insoluble portion, more solvent is added, stirred and the mixture is again centrifuged. This process is repeated until all the insoluble material is separated from the soluble portion of the crude oil. The insoluble portion of the asphaltenes obtained is then soxhlet extracted with the same solvent for 24 h to purify the asphaltenes.\(^ {15}\)

5.2.3 Bottom Sediments and Water

Centrifuging is a process in which the sample contained in a tube is subjected to a force which allows different phases of a mixture to separate from each other. Water and sediments are determined using a method in which a known amount of crude oil is mixed with a water-saturated solvent such as toluene. The mixture is shaken well and then centrifuged in a graduate glass tube at a rate of 1500 to 2000 rpm. The water and sediments are separated from the crude oil, collected at the bottom of the tube and then measured.\(^ {16}\)

5.2.4 Heavy Hydrocarbon Content

Supercritical fluid extraction is a method in which a sample is subjected to extraction by a solvent under supercritical conditions. This method is operated at low temperature using low boiling point solvents such as carbon dioxide as an extracting medium. This method provides the extraction of non-distillable portions of crude oils which are then analyzed using other techniques.\(^ {17}\)

5.2.5 Petroleum Resin Content

Petroleum resins are separated from the whole crude oil or heavy fraction using a liquid chromatographic separation method known as SARA. The abbreviation SARA
is derived from the abbreviations of the main fractions separated from whole crude oil, namely: saturates, aromatics, resins and asphaltenes. In this method, a glass percolating column is packed dry with anionic exchange material Amberlyst 29 at the bottom, and a ferric chloride bound kaolin clay layer in the middle section. The upper part of the ferric chloride bound kaolin clay is packed with anionic exchange material Amberlyst 29 followed by cationic exchange material Amberlyst 15. The column is then purged with nitrogen gas flow followed by \(n\)-pentane elution and recycling to remove air bubbles and impurities of the packing materials. A weighed quantity of the sample is placed in a cellulose thimble and introduced into the top reservoir of \(n\)-pentane. The maltenes present in the sample are dissolved in \(n\)-pentane, leached out of the thimble and carried into the column while \(n\)-pentane-insoluble asphaltenes remain in the thimble. The resins are retained on the column while the oil remains unretained and collects in the bottom flask. Chloroform elution is then used to remove the resins from the column and then evaporated under nitrogen to recover the resins.

### 5.3 Fractionation

Crude oil is a complex mixture of hydrocarbons and nonhydrocarbon-containing sulfur, nitrogen, oxygen and metals such as vanadium, nickel and iron. Crude oil is so complex that it contains basic as well as acidic compounds at the same time. The complexity of crudes increases with increasing boiling point. This is because as the carbon number of molecules increases, the number of isomers increases exponentially. The complexity is also enhanced due to the presence of heteroatomic and metallic compounds. Due to this complexity, crude oils are separated into fractions based upon the type of information required. There are several separation schemes used to produce fractions containing specific compound types. For example, the ion-exchange resins are used to separate acidic and basic compounds whereas ferric chloride–Attapulgus clay complex separates neutral nitrogen compounds.

The United States Bureau of Mines (USBM)–API method\(^{[19]}\) provides separation of heavy distillates of a crude oil into saturates, acids, bases, neutral nitrogen compounds and monoaromatic, diaromatic and polyaromatic compounds. This method combines ion-exchange, coordination and adsorption chromatography and the recycling chromatographic column used for this method is illustrated in Figure 2. The crude oil sample is first distilled to produce the distillate which is passed through a glass column having anion resins where the acidic compounds are retained by the resin and other components are washed from the resin by the solvent. The retained acids are removed from the resins using elution with benzene, followed by methanol and finally with methanol saturated with carbon dioxide. Similarly, the acid-free sample is passed through a column of cationic resin to separate basic compounds from the sample. The retained bases are removed from the resin using elution with benzene, followed by methanol and finally with methanol mixed with isopropylamine. The neutral nitrogen compounds are separated by passing the sample through a column having ferric chloride–Attapulgus clay at the top and anion resin at the bottom. The nitrogen compounds are retained by making a complex with the ferric chloride–Attapulgus clay while the aromatics are washed. The retained nitrogen compound–ferric chloride complex is removed by dichloroethane elution and then broken down on contact with anion resin into ferric chloride and nitrogen compounds. The salt is retained by the resin while the nitrogen compounds are recovered. The sample left after acid, base and neutral nitrogen compound removal is chromatographed on a column packed with alumina gel in the bottom and silica gel at the top and eluted with nonpolar to polar solvent. Saturates are eluted using \(n\)-heptane elution, followed by \(n\)-heptane containing 5% benzene elution to remove monoaromatics. Diaromatics are separated by increasing the benzene content of the solvent to 15% and finally the polyaromatics are eluted with methanol containing 25% benzene and 25% ether.
5.4 Distillation

The distillation of a crude oil is carried out to determine the boiling range distribution of a crude oil as well as collection of fractions for further characterization using different analytical techniques. This is an important requirement in the preparation of an assay of a crude oil. This information is used to estimate the yield of refinery products and thus the economics of using a crude oil in the refinery. The distillation is carried out by a combination of TBP distillation and vacuum distillation.\(^{20,21}\) This process is also called physical distillation to distinguish it from simulated distillation. During physical distillation, the crude oil is distilled into various fractions based upon the desired boiling range and it is accomplished in two steps: TBP distillation\(^{20}\) and distillation under vacuum.\(^{21}\) The TBP distillation of whole crude oil is achieved using an apparatus having a distillation column equivalent to 16 theoretical plates and operated at a 5 : 1 reflux ratio.\(^{20}\) The distillation unit is provided with a boiler in which the crude oil is heated, a distillation column, a distilled fraction collector with receivers, a vacuum pump and a refrigeration unit. The distillation unit is equipped optionally with an electronic pressure sensor and a photoelectric level follower to measure the volume of distillate and distillation rate. As a first step, the absorbed gases and moisture present in the crude oil are removed from the sample before distillation and this process is called debutanization. The debutanization is performed under vacuum at 25°C and the removed gases are trapped under cryogenic conditions. Following the debutanization of crude oil, the distillation is carried out under atmospheric pressure and increased temperature. The temperature of the crude oil in the boiler should not exceed 345°C. Above this temperature, thermal cracking of the petroleum hydrocarbons is evident and therefore the distillation is carried out under reduced pressure. This is because at this temperature the energy required to distill a fraction exceeds the energy required to break C—C, C—H, C—S and C—N chemical bonds. The TBP distillation is carried out up to 400°C atmospheric equivalent temperature (AET). The residue from the TBP distillation process is further distilled to produce high boiling distillates and residue.\(^{21}\) This process, called vacuum distillation, is performed under reduced pressure using equipment consisting of a boiler, short column having a minimum pressure drop, a high vacuum system and a distillate receiver. The vacuum distillation is carried out up to 600°C AET as a batch process. The collected fractions are measured and the distillation curve is prepared: per cent distilled crude oil as a function of temperature. Another method to carry out distillation under vacuum is called short path distillation. In this method, the preheated residue from atmospheric distillation is pumped at a defined rate onto the surface of a heated vertical cylinder in the evaporation chamber where it is spread by wipers into a thin, uniform and downward-falling film. The lower boiling components of the film are flash evaporated and collected in a condenser, while the higher boiling components move downward and are collected as the residue. As compared to vacuum distillation using a packed column, the short path distillation is carried out under higher vacuum, a continuous process, shorter residence time, and a shorter distance between heated and condensing surface. These factors allow very deep distillation of the residue without decomposition and a distillate fraction up to 700°C AET is easily prepared.

5.5 High-performance Liquid Chromatography

HPLC of whole crude oil is performed to determine the amount of saturates (paraffins and naphthenes), aromatics and polars. The crude oil is first treated with an n-alkane solvent such as n-hexane to precipitate the asphaltenes. The resulting mixture is filtered through a 0.5-µm membrane filter to remove asphaltenes (n-alkane insolubles) from maltenes (n-hexane solubles). The maltenes are further fractionated using HPLC into saturates, aromatics and polars on an aminopropyl packed column. The saturates are eluted first followed by aromatics. When the aromatics are completely eluted the column is backflushed to elute the polar fraction from the column. A complete analytical HPLC run requires 30 min to elute saturates, aromatics and polars. HPLC is operated both in analytical and preparative modes. A typical HPLC system consists of sample injector, solvent delivery system, column, ultraviolet detector and a differential refractometer detector. The analytical HPLC method is used to obtain areas of saturates, aromatics and polars present in the sample solution. The saturates are detected by refractometer detector while the aromatics and polars are detected by ultraviolet detector.\(^{22}\) In order to collect the fraction from HPLC for further characterization using other techniques, the preparative scale HPLC method is used. The preparative HPLC method employs wider bore columns in which a higher amount of sample can be injected, separated and the fractions collected. The collected fractions are purified by removing solvent under reduced pressure and then weighed. In another method, the whole crude oil is separated into six hydrocarbon types using a normal phase multidimensional HPLC method equipped with two columns and two switching valves. The detection of the fractions is achieved using two detectors: photodiode array detector (PAD) and evaporative light scattering detector (ELSD). These six hydrocarbon types are
1. saturates;
2. monoaromatics (1-ring);
3. diaromatics (2-ring);
4. triaromatics (3-ring);
5. quadaroaromatics (4-ring);
6. polars which include 5+ rings and N- and O-heterocyclics.

The elution of components is carried out using a gradient elution program in which three solvents, namely $n$-hexane, dichloromethane and isopropanol, are used. Pure $n$-hexane is used to separate saturates and monoaromatics on a column packed with propylaminocyano (PAC) stationary phase. The aromatics are separated on a dinitroanilinopropyl (DNAP) packed column and the polarity of the solvent is gradually increased by increasing the concentration of dichloromethane in $n$-hexane. When all the aromatics are eluted, a mixture of dichloromethane and isopropanol is used to elute the polars from the column. Both columns are regenerated using a reverse elution program using all three solvents.

5.6 Gas Chromatography

GC of a crude oil is performed to obtain different types of information which include determination of boiling range distribution using simulated distillation, individual component identification and identification of the source of a spilled crude oil using fingerprint chromatograms.

5.6.1 Determination of Boiling Range Distribution by Simulated Distillation Method

Simulated distillation is a method in which the process of physical distillation is simulated using gas chromatographic separation of the components of the sample. This method determines the boiling range distribution of a moisture-free crude oil up to 538 °C and the material boiling above this temperature is termed residue. In this method, the crude sample is dissolved in carbon disulfide and injected into a gas chromatographic column which separates the hydrocarbons according to their boiling points. Both packed columns as well as capillary are used for separating the components. The column temperature is increased in a linear fashion and the area under the whole chromatogram is recorded. Prior to the sample run, a standard mixture of $n$-paraffins ($n$-C$_5$ to $n$-C$_{40}$), having a boiling range from 36 to 525 °C, is chromatographed under the same conditions to provide a correlation between the retention time and boiling point. A comparison of the chromatogram of standard with the sample assigned boiling points to the time axis of the sample components. The amount of residue is estimated by making a second run of the crude oil sample having a known amount of internal standard consisting of C$_{14}$, C$_{15}$, C$_{16}$ and C$_{17}$ normal paraffins. Using these data, the boiling range distribution of the crude oil sample is calculated and reported as percent distilled versus temperature including IBP and FBP of the sample. IBP and FBP are the temperatures at which 0.5% and 95.5% of the material is eluted from the column, respectively. Figure 3 shows a simulated distillation chromatogram of Arab Berri crude oil. This method is developed further to increase the FBP of the method up to 750 °C and it is called a high temperature simulated distillation. With the introduction of high temperature resistance materials for column preparation, stationary phases and GC oven construction material, the simulated distillation is capable of analyzing crude oils up to C$_{120}$. In this method, an ultimetal capillary column having an operation temperature stability of 450 °C is used. This column is coated with linear polydimethylsiloxane as stationary phase and temperature programmed up to 450 °C; the hydrocarbons with boiling point up to 750 °C are then separated and identified. In order to obtain the boiling range distribution of sulfur compounds in crude oils along with hydrocarbons, a post-column splitter is utilized to achieve detection simultaneously by both a sulfur chemiluminescent detector (SCD) and a flame ionization detector (FID). A comparison of simulated distillation with physical distillation to determine the boiling range distribution of a crude oil shows that the simulated distillation incorporates a high level of automation and thus requires very little operator involvement. Besides, a single boiling range distribution analysis using physical distillation requires two to five
days whereas a complete simulated distillation analysis needed 30 min. The automation in simulated distillation analysis assures a reproducibility of 2–3°C compared to 10–30°C in the physical distillation process. The faster analysis time, better reproducibility and equivalent results are some of the advantages of simulated distillation over physical distillation.\(^{29}\)

5.6.2 Volatile Compound Identification

The individual component identification of a crude oil is performed for volatiles using a backflushing valve system coupled with a GC system. The whole crude oil is introduced into a system with a backflushing valve. When the volatile elution is complete, the sample injected is backflushed to remove the heavy components from the column. Fast analysis of light hydrocarbons present in crude oils is performed using the switching valve, separation at sub-ambient conditions and fast temperature programming. Standard mixtures of hydrocarbons containing volatiles are used to determine the appropriate temperature and switching valve timing of the method. The crude oil is injected and the hydrocarbons up to nonane are eluted while the heavier components are prevented from entering the analytical column and sent to a system vent. This technique permits separation at sub-ambient temperatures in minimum time and the life of the column is extended.\(^{30}\)

5.6.3 Oil Spill Identification

GC is also used to identify the source of oil spill. In this method, the whole crude oil is injected into a GC column with an FID. This technique provides a chromatogram having a pattern of peaks characteristic of that particular crude provided that the operating conditions remains same. An unknown or suspected spilled crude oil sample is identified by comparing its chromatogram with the standard chromatograms available for potential source crude oils. Using this technique, the source of oil spill is identified. Two-dimensional GC is used to provide better separation and identification of the crude oil components which provide both quantitative and qualitative comparison between the oil spill and the potential source crude.\(^{31}\) The two-dimensional GC is combined with MS to identify the individual compounds present.\(^{32}\)

5.6.4 Pyrolysis Gas Chromatography

PGC (pyrolysis gas chromatography) is a technique which provides a rapid assay of crude oil without initial treatment. This technique provides fingerprints of different crude oils for comparison purposes. In PGC, the crude oil sample is heated in a chamber to break the large molecules into smaller volatile molecules which are then separated in a gas chromatograph and characterized easily using an FID. Other detectors such as an NPD (nitrogen phosphorus detector) or an FPD (flame photometric detector) are also used for nitrogen and sulfur compound identification. A comparison of PGC and MS shows a similarity between the two techniques. In PGC, the large molecules are broken down into smaller molecules using thermal energy, whereas in MS this is done using electron impact or chemical ion impact. The molecular fragments are separated in PGC using GC whereas separation of ions is achieved in MS using a strong magnetic field. In PGC, the detection is achieved using an FID and appeared in the form of a chromatogram, whereas in MS the ions are collected and registered in the form of a profile of ions generated which is called a mass spectrum. PGC can be combined with MS to provide a better identification of the fragments obtained during pyrolysis of crude oil.\(^{33}\)

5.7 Supercritical Fluid Chromatography

SFC is a chromatographic method in which the sample dissolved in carbon disulphide is injected onto a packed silica adsorption column and eluted using a highly pressurized mobile phase such as carbon dioxide. Different compounds of the sample are separated and detected using a suitable detector such as an FID. Compared to GC, SFC has the advantage of possessing a much higher solubilizing power than a gas which allows higher molecular weight and ionic compounds to be chromatographed at lower temperatures. In comparison to LC, the SFC mobile phase exhibits more desirable transport properties resulting in a significant reduction in the resistance to mass transfer in the mobile phase. Other mobile phases used in SFC include nitrous oxide, methanol, \(n\)-propane, \(n\)-butene, \(n\)-pentane, dichlorodifluoromethane and trichlorofluoromethane. SFC is used in the separation of polynuclear aromatic hydrocarbons and vacuum residue as well.\(^{34}\)

5.8 Mass Spectrometry

In MS, the crude oil sample is placed in a vacuum chamber where a variety of methods are applied to convert the molecules into ions. These methods include fragmenting methods such as electron impact mass spectrometry (EIMS) as well as nonfragmenting techniques of field desorption mass spectrometry (FDMS) and field ionization mass spectrometry (FIMS). The ions are passed through a magnetic field and are separated according to their mass/charge ratios. The ions are collected and registered for the type and amount present in the stream. The pattern obtained after detection of ions, called the mass spectrum, is then compared with the known mass spectrum of pure compounds to find the type of compounds present in crude
oil. The mass spectrum of a crude oil is very complex since thousands of compounds belonging to different classes are present. In practice, mass spectra of the crude oil fractions are obtained which are quite useful and provide valuable information regarding the components present.\(^{35}\) Low voltage high resolution is another MS method applied to distinguish between molecules of equal masses. Using this method, a nitrogen atom is easily distinguished from a CH\(_2\) group.\(^{36,37}\) The mass spectrometer coupled with GC as a detector is called GC/MS. In this technique, the compounds eluted from the GC column enter into the mass spectrum and are fragmented into ions. These ions are detected and produce a profile or mass spectrum of the compound which is then compared with mass spectra of known compounds to find its identity. The GC/MS of the whole crude is impractical since the heavy hydrocarbons present in the crude oils are not eluted from GC.

5.9 Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy analysis of a crude oil is performed to determine the type and amount of hydrogen and carbon present. NMR analysis can distinguish whether the hydrogen or carbon is attached to an aliphatic, naphthenic or aromatic type of hydrogen or carbon atom. This leads to the determination of percent paraffinic, naphthenic and aromatic hydrogen and carbon present in the crude oil. This information is quite helpful to differentiate paraffinic, naphthenic and asphaltic types of crude oils. NMR spectroscopy provides structural parameters of crude oils which can produce a detailed analysis when combined with other properties. NMR spectroscopy is performed by dissolving the sample in deuterated chloroform and adding trimethylsiline as a reference. The deuterated chloroform acts as a solvent as well as a locking agent. An NMR spectrum of crude oil is achieved by recording a magnetic resonance signal of a diluted sample in the presence of a very strong magnetic field. The combination of proton and carbon-13 NMR along with elemental analysis of crude oil allows the determination of a number of average structural parameters such as total aromatic and aliphatic carbon, naphthenic and paraffinic carbon, the number and length of paraffinic carbon chains, the degree of chain branching, the number of aromatic methyl substituents, the aromatic ring size and the degree of aromatic ring substitution.\(^{38,39}\)

5.10 Infrared Spectroscopy

IR spectroscopy is used to characterize crude oils mostly in terms of oxygen and nitrogen containing functional groups. Using IR spectroscopy, acids and bases such as carboxylic acids, phenols, carbazoles and cyclic amides present in the petroleum mixtures are quantified. The type of solvent in which the crude oil is dissolved has a marked effect on the detection of different compounds. For example, tetrahydrofuran (THF) is used as a solvent to minimize association between carboxylic acids and amides and thus help in their detection in the IR spectrum.\(^{40,41}\) The concentration of hydroxyl compounds is identified using the peak absorption in the region 3540–3600 cm\(^{-1}\) of the IR spectrum. IR spectroscopy also determines the hydrogen bondings present between different functional groups such as OH and NH. This is done by recording the IR spectrum of the petroleum mixture at different concentrations in a number of solvents. At low concentration, the hydrogen bonding is less pronounced and the peaks of free OH (3610 cm\(^{-1}\)) and NH (3480 cm\(^{-1}\)) become visible.\(^{42}\) IR spectroscopy is also utilized in finding the distribution of H atoms in the aromatic rings and that of CH\(_2\) and CH groups in the aliphatic part of the hydrocarbons.

5.11 Thermal Analysis

Thermal analysis is used to study the characteristics of crude oils. During thermal analysis, a known quantity of crude oil is subjected to programmed heating in the presence of air or inert gas such as nitrogen. The crude oil sample loses moisture and volatile components by evaporation and the process behaves like the physical distillation during the initial heating. During the evaporation process, the heat is required by the molecules and thus endothermic peaks are observed in the thermogram. When the temperature of the crude oil exceeds 340°C, thermal degradation of the oil is started due to thermal cracking of the hydrocarbons. This is because at higher temperatures the energy provided to the crude oil is enough to break chemical bonds such as C–H, C–C, C–N and C–S present in the petroleum molecules. During thermal analysis, a number of phenomena such as evaporation, decomposition and oxidation take place in the crude oil. Oxidative degradation is characterized by an exothermic peak with corresponding weight loss. Evaporation requires heat and therefore appears as an endothermic peak in the thermogram. Using thermal analysis, the hydrocarbons of a crude oil can be classified into four types; the volatiles and low molecular weight, medium molecular weight and high molecular weight hydrocarbons. The volatiles are characterized by heat absorption leading to evaporation of these hydrocarbons. The other three types of hydrocarbons are identified by the presence of exothermic peaks in the thermogram as a result of oxidative degradation of these hydrocarbons. The volatile contents of crude oils are found more in lighter crude compared to heavier crude.\(^{43}\)

5.12 Elemental Analysis Method

The analysis of carbon, hydrogen, nitrogen and sulfur is very important in determining the complex nature and
type of the crude oils. Nitrogen and sulfur are very important from the processing and upgrading point of view and are determined to assess the performance of petroleum upgrading processes such as HDS and HDN. In a single instrumental method, carbon, hydrogen, nitrogen and sulfur are determined simultaneously. One of the standard methods describes the determination of carbon, hydrogen and nitrogen in petroleum products. The latest development also provides determination of sulfur along with carbon, hydrogen and nitrogen. In this method, the crude oil sample is introduced into the system where oxidative combustion takes place in an oxygen–helium atmosphere. As a result, the elements C, H, N and S are converted into CO₂, H₂O, NO, NO₂, SO₂ and SO₃ products. These gases are passed over a copper reduction tube where oxides of nitrogen are reduced to molecular nitrogen and sulfur oxides are converted to SO₂. After the reduction process, the gas mixture contains CO₂, H₂O, NO, NO₂, SO₂ and SO₃ products. These gases are then separated using an adsorption process in which each component is adsorbed on a separate adsorption column and finally detected individually by a thermal conductivity detector (TCD). The quantification of the elements is achieved through an external standard method.

The total sulfur content of crude oils and heavy products is also determined by burning a sample in a stream of air. The sulfur dioxide produced is further oxidized to sulfuric acid, which is titrated with a standard alkali. Identification of individual sulfur compounds in crude oils is not needed from the refinery point of view since it is time-consuming and all sulfur compounds practically are hydrodesulfurized to hydrogen sulfide and hydrocarbons. Total sulfur in whole crude oil is determined using a variety of methods which include XRF spectroscopy and the bomb method. All of these methods have specific limitations as well as variable detection limits. In XRF spectroscopy, the sample is placed in an X-ray beam and the resulting excited characteristic radiation is measured. By comparing the signal from the sample with multilevel concentration calibration samples, the amount of sulfur present in the sample is determined. In the bomb method, the sample is oxidized by electrical ignition and combustion in a pressurized bomb filled with oxygen. All the sulfur present in the sample is converted to oxides of sulfur which are then converted to barium sulfate and determined gravimetrically.

5.13 Atomic Absorption Spectrometry

AAS is used to determine quantitatively the amount of metals present in crude oils. Generally, two methods are used for sample preparation. The crude oil sample is mixed with a suitable solvent such as mixed xylenes to produce a dilute solution. In the other method, the crude oil is heated to burn and the carbon is removed finally by heating at high temperature in a furnace. The residue is fused with a lithium tetraborate/lithium fluoride mixture. The fused sample is digested in hydrochloric acid solution and diluted with water. The diluted solution containing the metals is then aspirated into an atomic absorption spectrometer having a lamp for a particular metal or group of metals. The absorption intensity of the solution is measured individually for all the elements. Prior to the measurement of each metal, the spectrometer is calibrated using a standard solution containing the particular metal. By comparing absorption intensities of the elements present in the crude oil solution with absorption intensities measured with the standard calibration solutions, the concentrations of elements in the crude oil sample are calculated. Using this technique, almost all of the metals present in the crude oil are determined. These include aluminum, barium, boron, calcium, chromium, copper, vanadium, nickel, iron, magnesium, phosphorus, potassium, sodium, silicon and zinc. AES is also utilized alone for the detection and measurement of sulfur and nitrogen in crude oils. Contrary to FPD, the AES sulfur response is linear, equimolar and exhibits little or no quenching. These characteristics help in determining the concentration of total sulfur as well as individual sulfur compounds. The calibration of the detector is done using a single sulfur compound. Using this detector, sulfur and nitrogen contents at low ppm levels are measured.
5.15 Chemiluminescent Detection Method

A chemiluminescent detector offers rapid quantitation of speciated sulfur containing compounds in crude oils or the total sulfur present. The detector is set up either to quantify compounds separated from the crude oil or for total sulfur measurement. In this method, the whole crude is separated from asphaltenes and injected into the HPLC column where it is separated into different hydrocarbon types. The sulfur compounds present in these separated fractions are then detected by the chemiluminescent detector which is internally or externally calibrated. These compound types are detected for the presence of sulfur on a linear and equimolar basis.\(^{(52)}\)

5.16 Titration Methods

A number of titration methods are used to determine different properties of a crude oil. These methods include determination of water content and acid and base compound concentration in a crude oil.

5.16.1 Water Content

The determination of water content is very important in the processing, transportation and purchase of a crude oil. Water content of a whole crude oil is determined using a number of methods depending upon the amount of water present in the sample. Trace quantities of water are determined by using a titration method in which the sample is titrated using Karl Fisher reagent to an electrometric end-point.\(^{(53)}\) Ultratrace amounts of water are determined using the coulometric Karl Fisher titration method. In this method, a weight quantity of a properly homogenized crude oil sample is injected into the titration vessel of the Karl Fisher equipment in which iodine is generated coulometrically at the anode. When all the water is titrated, the excess iodine is detected by an electrometric end-point detector and the titration is complete. Since 1 mol of water reacts with 1 mol of iodine stoichiometrically, the quantity of water present in the sample is proportional to the total integrated current.\(^{(54)}\)

5.16.2 Acid Number

The acid number of a crude oil is measured to determine the acidic constituents present, which include carboxylic acids and phenols. Acid number is defined as the measure of the amount of acidic substances present in the oil which can be determined by titration with bases under the given test conditions. In this method, a known amount of crude oil sample is dissolved in a mixture of toluene and isopropyl alcohol containing a small amount of water and titrated potentiometrically up to the end-point with alcoholic potassium hydroxide standard solution using a glass indicating electrode and calomel reference electrode.\(^{(55)}\)

5.16.3 Base Number

The crude oils contain basic constituents such as amides, pyridines, carbazoles, etc. Base number is defined as the measure of the amount of basic substances present in the oil which can be determined by titration with acids under the given test conditions. In this method, a known amount of sample is dissolved in an anhydrous mixture of chlorobenzene and glacial acetic acid and titrated with a solution of perchloric acid in glacial acetic acid using a potentiometric titrator. The potential readings are measured by means of a glass indicating electrode and a calomel reference electrode and the end-point is detected.\(^{(56)}\) The types of nitrogen compounds are determined using a scheme in which the sample is dissolved in a mixture of acetic anhydride and benzene in the ratio 2:1 and titrated with 0.05 M perchloric acid prepared in 1,4-dioxane using a glass indicating electrode and a calomel reference electrode system. A number of end-points are detected which indicate the types of nitrogen compounds titrated. Using this method, the nitrogen compounds are classified into strong bases, weak bases and nonbasic types.\(^{(57)}\)

FULL RANGE CRUDES, ANALYTICAL METHODOLOGY OF

Simulated distillation (SimDist) is a gas chromatography (GC) technique which separates individual hydrocarbon components in the order of their boiling points, and is used to simulate the time-consuming laboratory-scale physical distillation procedure known as true boiling point (TBP) distillation. The separation is accomplished with a nonpolar chromatography column using a gas chromatograph equipped with an oven and injector that can be temperature programmed. A flame ionization detector (FID) is used for detection and measurement of the hydrocarbon analytes. The result of SimDist analysis provides a quantitative percent mass yield as a function of boiling point of the hydrocarbon components of the sample. The chromatographic elution times of the hydrocarbons are calibrated to the atmospheric equivalent boiling point (AEBP) of the paraffins reference material. The SimDist method ASTM (American Society for Testing and Materials) D2887 covers the boiling range 55–538°C (100–1000°F) which covers the n-alkanes (n-paraffins) of chain length about C5–C44. The high-temperature simulated distillation (HTSD) method covers the boiling range 36–750°C (97–1382°F) which covers the n-alkane range of about C5–C120. A key difference between ASTM D2887 and HTSD is the ability of the latter technique to handle residue-containing samples (i.e. material boiling > 538°C, 1000°F). SimDist and laboratory-scale physical distillation procedures are routinely used for determining boiling ranges of petroleum crude oils and refined products, which include crude oil bottoms and residue processing characterization. The boiling point with yield profile data of these materials are used in operational decisions made by refinery engineers to improve product yields and product quality. Data from SimDist are valuable for computer modeling of refining processes for improvements in design and process optimization. Precise yield correlations between HTSD and crude assay distillation (methods ASTM D2892 and D5236) have allowed HTSD to be successfully used in place of physical distillation procedures. This has given the refiner the ability to rapidly evaluate crude oils for selection of those with economic advantages and more favorable refining margins. SimDist methods are becoming more widely used in environmental applications. HTSD is useful for characterizing hydrocarbons which can be present as soil and water contaminants; for example, to map and follow hydrocarbon removal processes.
1 INTRODUCTION

SimDist is a GC technique which separates individual hydrocarbon components in the order of their boiling points, and is used to simulate time-consuming laboratory-scale physical distillation procedures. The separation is accomplished with a chromatography column coated with a nonpolar (hydrocarbon-like), stationary phase, and uses a gas chromatograph equipped with an oven and injector which can be temperature programmed. A FID is used for detection and measurement of the hydrocarbon analytes. The SimDist analysis result provides a quantitative percent mass yield as a function of boiling point of the hydrocarbon components of the sample being analyzed. The chromatographic elution times of the hydrocarbon components are calibrated to the AEBP of the \( n \)-alkane as described in a method from the ASTM (1) by using \( n \)-alkane (\( n \)-paraffin) reference material. In the SimDist method ASTM D2887, (1) the \( n \)-alkane calibration reference covers the boiling range 55–538 °C (100–1000 °F) which covers the \( n \)-alkanes with a chain length of about \( C_5 \)–\( C_{44} \). In the HTSD method, the \( n \)-alkane calibration reference (a hydrogenated polyolefin wax, polywax 655) covers the boiling range 36–750 °C (97–1382 °F) which covers the \( n \)-alkanes with a chain length of about \( C_5 \)–\( C_{120} \). A key difference between ASTM D2887 and HTSD is the ability of HTSD to handle residue-containing samples (i.e. material boiling > 538 °C or 1000 °F).

SimDist and laboratory-scale physical distillation methods are routinely used for determining boiling ranges of petroleum crude oils and refined products. The boiling point with yield profile data of these materials are used in operational decisions made by refinery engineers to improve product yields and product quality. SimDist is valuable for, and can improve results from, computer modeling of refining processes for improvements in design and process optimization. Precise yield correlations between HTSD and crude assay distillation (a procedure which uses methods ASTM D2892 (2) and D5236 (3)) have allowed HTSD to be successfully used in place of physical distillation procedures. This can result in economic advantages for the refiner in the selection of crude oils, with more favorable refining margins. SimDist methods are also now becoming more widely used in environmental applications; for example, in characterizing hydrocarbons which can be present as soil and water contaminants.

2 HISTORY

SimDist was reported early in the 1960s by Eggertsen et al. (4) and Green et al. (5,6) as a method of simulating the time-consuming laboratory-scale physical distillation “TBP” procedure (7) by using GC. The SimDist technique is based on the fundamental assumption that individual nonpolar hydrocarbon components of a sample elute in the order of their boiling points from a GC column coated with nonpolar (hydrocarbon-like), stationary phase. The elution, or retention, time is dependent upon vapor pressure of the component and its affinity for the stationary phase. This varies with different types of hydrocarbons. For example, aromatic hydrocarbons and cycloalkanes (naphthenes) generally elute earlier than \( n \)-alkanes having the same boiling points. In SimDist, conditions are selected to give limited column efficiency and resolution unlike other chromatography techniques, which generally aim for highly efficient conditions that achieve high-resolution separation of components. The lower resolution analysis conditions provide distillation data that agree with physical distillation.

SimDist became an ASTM standard method in 1973, with the designation D2887, “Boiling Range Distribution of Petroleum Fractions by GC”. The current edition is designated D2887-97. This method covers the determination of the boiling range distribution of petroleum products and fractions having a final boiling point (FBP) of 538 °C (1000 °F) or lower at atmospheric pressure.

HTSD is a relatively recent method which extends ASTM D2887 determination of the boiling range distribution of hydrocarbons to a FBP of about 750 °C (1382 °F). Technological advances in capillary GC columns and stationary phases together with either programmed temperature vaporization (PTV) or on-column injection techniques, provide adequate separation from \( C_5 \) to \( C_{120} \) normal paraffins and allows the characterization of petroleum products from about 36–750 °C (97–1382 °F). Under the special conditions of HTSD, elution of materials from the GC column occurs at up to 260–316 °C (500–600 °F) below their AEBP. For instance, the elution of \( C_{110} \) (AEBP of 735 °C or 1355 °F) occurs at a column temperature of about 427 °C (800 °F). Also under these conditions, little or no evidence of cracking is normally seen in HTSD.

3 COMPARISON OF AMERICAN SOCIETY FOR TESTING AND MATERIALS DISTILLATION AND SIMULATED DISTILLATION METHODS

A summary of ASTM physical distillation and SimDist methods is presented schematically in Figure 1 and discussed in detail below.

3.1 Physical Distillation Methods

Laboratory-scale physical distillation methods are routinely used by petroleum refineries for determining
the boiling ranges of crude oils and their products. ASTM D86(8) has been used as a quality control (QC) test since the 1920s. This method is a one-plate distillation that covers the range of materials boiling up to about 254 °C (490 °F). ASTM D1160(9) is a similar method but is conducted at reduced pressure and covers the determination of the range of boiling points for petroleum products that can be partially or completely vaporized at a maximum liquid temperature of 400 °C (752 °F). This temperature corresponds to an atmospheric equivalent (vapour) temperature of about 600 °C when run under 1 mmHg (the lowest pressure permitted). Petroleum products and fractions in this range may decompose if distilled at atmospheric pressure. ASTM D2892(2) is used for samples with a wide boiling range such as crude petroleum up to a final cut temperature of 400 °C (752 °F) atmospheric equivalent temperature (AET). The method can also be applied to any petroleum mixtures except liquefied petroleum gases, very light naphthas, and fractions having initial boiling points (IBPs) above 400 °C. This test method uses a fractionating column having an efficiency of 14–18 theoretical plates operated at a reflux ratio of 5:1 for the production of liquefied gas, distillate fractions, and residuum. The method provides for the determination of yields of material as both mass and volume. A graph of temperature versus mass-percent distilled can be produced, and this distillation curve corresponds to a laboratory technique which is defined at 15/5 (15 theoretical plate, 5:1 reflux ratio) or TBP. ASTM D5236(3) is for distillation of heavy hydrocarbon mixtures such as heavy crude oils, petroleum distillates, residues, and synthetic mixtures with IBPs greater than 150 °C (300 °F). This method provides for the determination of standard distillation curves to the highest AET possible by conventional distillation. The maximum achievable temperature up to 565 °C (1050 °F) AET is dependent upon the heat tolerance of the charge.

3.2 Simulated Distillation Methods

SimDist methods which have been adopted as ASTM test methods are D2887(11) D3710(10) and D5307(11). Method D2887-97 covers the determination by GC of the boiling range distribution of petroleum products and fractions having a FBP of 538 °C (1000 °F) or lower at atmospheric pressure. Method D3710-95 covers the determination by GC of the boiling range distribution of gasoline and gasolene components with a FBP 260 °C (500 °F) or lower. D5307-97 is for the determination by GC of boiling range distribution of crude petroleum through 538 °C (1000 °F), with material boiling above 538 °C being reported as residue.

HTSD by GC, which is currently under ASTM Committee D-2 proposed development status, is an extension of ASTM method D2887 for application to petroleum products and fractions, and materials containing higher boiling range materials above 538 °C (1000 °F). This method is used for determining the boiling point distribution of petroleum products and fractions in the range up to about 732 °C (1350 °F) at atmospheric pressure, and reports material boiling higher than this as material boiling >732 °C (1350 °F). The method is applicable to a wide range of fully eluting and non-completely eluting materials, which include petroleum crude oil, cat crack feed and product, hydrotreater feed and products, atmospheric residue, vacuum gas oils, deasphalted oils, and vacuum tower bottoms (pitch).

4 METHODOLOGY

By the proper choice of GC conditions and equipment in HTSD, separation in the boiling range from C₆ to C₁₂₀ n-alkanes is carried out routinely. To accomplish the goal of eluting heavy materials up to the equivalent of C₁₂₀, a thin film of column nonpolar stationary phase is used. The film thickness varies from 0.05–0.15 m, which, with a 0.53 mm internal diameter (ID) capillary column results in a phase ratio (volume of the column vs the volume of the stationary phase) high enough to permit the elution of materials from the column at temperatures up to 260–316 °C (500–600 °F) below their AEBP.

GC instrumentation for HTSD is typically equipped with a PTV injector and FID. The analysis is carried out with a relatively short capillary column about 5 m length, 0.53 mm ID, and 0.05–0.15 μm film thickness. The temperature conditions of the column oven and injector are set initially at either near ambient or sub-ambient (−20 °C) and then programmed at a specified linear rate to a final temperature of about 430 °C. Sub-ambient initial conditions are generally required to cover a wide boiling range of samples. Helium carrier gas is used. The detector
signal is recorded as area slices (time intervals) for consecutive increasing retention times. SimDist software is used for data acquisition and results calculations.

4.1 Sample Preparation
A consequence of the conditions necessary for HTSD is a limited concentration capacity of the column due to the small amount of stationary phase. This requires appropriate dilution of the standards and samples (usually in carbon disulfide). Liquid hydrocarbon samples such as petroleum crude oils, gas oils, and solid or semi-solid residue materials, such as vacuum tower bottoms and asphaltic materials, are typically prepared at a concentration of about 2 mass percent in the solvent. Environmental samples such as oil-contaminated soils and waters are generally prepared at higher concentrations on the order of about 50 mass percent solvent to sample to improve sensitivity.

4.2 High-temperature Simulated Distillation Analysis
Because of the highly inert conditions of high-purity fused silica and special treated metal GC columns, the gentle injection techniques, and the short time at maximum temperature, little or no evidence of cracking is normally seen in HTSD. Because of the column breakdown (bleed) during the final portion of an HTSD analysis and the need to dilute the sample to approximately 1–2%, a blank GC run using only the solvent is recorded in the data system. This solvent blank is then subtracted from all subsequent GC runs in the analysis sequence of calibration, QC, and samples (Figure 2). This blank subtraction accomplishes

![Figure 2](image-url) Analysis of carbon disulfide solvent blank by using HTSD.

---

![Figure 3](image-url) Analysis of C₅ – C₁₁₀ n-alkane calibration reference mixture by using HTSD.
two important goals: (1) it removes the signal present for the solvent, which occurs just following the start of the analysis near the determination of any light end material present; and (2) the column bleed is compensated. The assumption during this process is that the solvent blank and the column bleed profiles are constant during the calibration and sample analysis. It is the HTSD operator’s duty to verify this criteria for statistically meaningful results.

4.3 Calibration

The HTSD calibration involves the analysis of (1) \( n \)-alkane calibration reference (hydrogenated polyolefin wax, polywax 655 which covers the boiling range \( C_5 \text{–} C_{120} \)) as shown in Figure 3, and (2) a reference oil that has been physically distilled by methods ASTM D2892 and D5236, as shown in Figure 4.

The polywax is used to calibrate chromatography elution times of the hydrocarbon components to the AEBP of the paraffin. The physically distilled reference oil is used as an external standard to calibrate the chromatography system for all sample percent recovery calculations. In addition, the HTSD analysis results found for the reference oil are compared to the mass distribution data known from physical distillation of the reference oil, and the statistical error of the difference between HTSD data versus actual boiling point data is reported (Table 1).

4.4 Determination of Hydrocarbon Yield as a Function of Boiling Point

The HTSD analysis result gives a chromatogram of detector signal response as a function of chromatography retention time, and a tabulated report of boiling point distribution of hydrocarbon yield at specific boiling cut-points in cumulative percent mass of sample (Figure 5, and Table 2). The report shows percent mass of material recovered in the analysis, IBP, FBP, and whether material boiling at higher than 732 °C (1350 °F) is present. The IBP is the temperature (corresponding to the retention time) at which a cumulative yield is equal to 0.5% of the total sample. The FBP is the temperature (corresponding to the retention time) at which a cumulative yield is equal to 99.5% of the total sample. The HTSD result can also be expressed in a carbon number distribution format which gives a graphical plot and tabulated report of yield at each \( n \)-alkane carbon number in incremental and cumulative percent mass (Figure 6).

of HTSD and statistically meaningful results. The QC includes the initial analysis for calibration of the reference oil that has been physically distilled by methods ASTM D2892 and D5236. As discussed in section 4.3 above, the HTSD yield with boiling point results for the reference oil are compared to the physical distillation mass distribution data, and the statistical error of the difference between HTSD data and the data by physical distillation is calculated and compared with acceptance limits established for the HTSD method.
Statistical analysis of QC samples is done with materials such as:
- a blend of physically distilled gas oils,
- lube feed stocks,
- hydrotreated residue,
- crude oils of different specific gravity (for example, California crudes and Gulf of Mexico crudes).

For each (QC) sample, the mean and standard deviation (SD) of the temperature vs percent yield is tracked over time. Using an X-type control chart, any excursions beyond ±2 or 3 SD limits will signal an out of control range method (Figures 7 and 8). Appropriate maintenance and corrective action is triggered before a sample analysis is reported.
5.2 Instrument Performance and Maintenance

Careful operator evaluation of the system performance is a condition for accurate HTSD data. Visual inspection of the n-alkane calibration reference is useful in evaluating system performance. Chromatographic peak shape symmetry of the n-alkanes and changes in their retention times can give an indication of the condition of the chromatography column and also the GC injector liner. The solvent blank analysis is also important in monitoring any shifts in baseline during the analysis.

Performance is affected by variables such as loss of the stationary phase at high temperatures (i.e. resulting in loss of film thickness and sample capacity) and the unavoidable build-up from residue containing samples of nonvolatile materials, such as metals, and asphaltenes in the injector and the column. Corrective action often involves replacing the GC injector liner, cutting off a short length of the column at the inlet, or replacing the column with a new one.

5.3 Interlaboratory “Round-robin” Test Results

Since HTSD is currently under ASTM proposed method status, methodologies that are followed in conducting this analysis vary. Users of the technique generally follow a manufacturer’s recommended practices for their particular instrumentation. Interlaboratory “round-robin” testing of HTSD draft methods and ruggedness studies for reproducibility are under investigation by ASTM Committee D-2 Study Group and internally by petroleum refining companies that use the technique. The data in Table 3 (provided by Royal Dutch/Shell Laboratories) show interlaboratory round-robin results for five different crude oils by six laboratories. The percent mass of hydrocarbon yield with temperature are given for each crude type and laboratory. Statistical analysis of the data shows the averages, SDs, relative SDs, and the overall average SDs for the HTSD analyses. As shown, precision is best at the cut point yields of 20%, 50%, and 70%, and is lower near the beginning and end cut points of 10% and 90%. The relative SDs of the total percent recoveries of material in the range <720 °C (corresponding to the boiling point of n-alkane C_{100}) ranged from about 1% to 5% for the different crude oils tested.

6 PETROLEUM REFINING APPLICATIONS

Distillation is the primary separation process used in crude-oil refining. Although the refinery unit has some nonideality that is not seen in laboratory-scale distillation, laboratory distillation is valuable in simulating the actual plant process. Laboratory analysis data on refinery process streams are often relied on as part of evaluation of unit performance. Process improvement and optimization decisions can be made with the help of laboratory test results that relate to plant occurrences.

6.1 Atmospheric Crude Distillates

Most atmospheric crude units produce atmospheric gas oil (AGO) product for hydrocracker or fluidized catalytic cracker (FCC) feed. A well-designed and proper operating unit will produce AGO with only barely detectable levels of metals present. Generally no volatile metals are found in AGO. Some units, however, produce AGO with relatively high levels of undesirable metals, such as...

30 ppm mass nickel plus vanadium caused from entrained residue.\textsuperscript{(12)} An example of estimating an entrainment level is to fractionate AGO by ASTM D5236 into two cuts containing the first 95 volume percent and final 5 volume percent. HTSD results, along with results from metals analysis methods, can then be used to help quantify the residue entrainment.

6.2 Crude Vacuum Distillates

Crude vacuum column units produce heavy distillate for downstream processing in an FCC or hydrotreater. Knowing the feedstock distillation curve slope and incremental gas oil contaminants is valuable for optimizing production of heavy vacuum gas oil (HVGO). Understanding contaminant distribution and HVGO product quality is important. For many crudes, high amounts of volatile metals and residue can lead to downstream catalyst poisoning. Laboratory analysis data is important for measuring HVGO yields and quality at different cut points and to determine feedstock contaminant distributions for predictive design work. Distillation curve data for vacuum column feedstocks are obtained in the laboratory by using various distillation techniques such as column distillation, short-path distillation, and SimDist by GC.\textsuperscript{(12)} Column distillation includes spinning-band distillation, batch distillation (ASTM D5236), and continuous-flash vaporization. Physical distillation methods result in overlap between cuts and resultant inaccuracy in the contaminant distribution curve. HTSD analysis of each cut allows the contaminant curve to be corrected for overlap. An example of this application of HTSD is shown in Figure 9. In another example as shown in Figure 10, HTSD was used to characterize seven laboratory preparative high vacuum distillation fractions at 25 °F cut points. The HTSD result can determine both the median boiling point of each fraction and also the preparative distillation efficiency or dispersion. With the boiling range of the preparative fraction precisely defined by HTSD and data concerning the properties, obtained by conducting other analyses on the preparative fractions such as density, asphaltenes, Conrad Carbon, and metals, useful vacuum tower optimization models for specific feeds and specific catalyst poisons can be developed.

6.3 Resid Processing Characterization

Crude oil bottoms present challenges to refiners who need to effectively convert them into useful products. Among the many “bottom of the barrel” processes available, solvent deasphalting is predominantly used to recover high-value deasphalted gas oil (DAO) from petroleum resid. DAO is excellent feedstock for lube oil, fluid catalytic cracking, and hydrocracking. The residuum oil supercritical extraction (ROSE\textsuperscript{™}) process licensed by Kellogg Brown & Root is a state-of-the-art solvent extraction process widely used in the industry today.\textsuperscript{(13)} HTSD is a useful tool for characterizing hydrocarbons by using boiling point profiles of fractions from the resid solvent extraction process.

The HTSD data presented in Figure 11 and in Table 4 show the chromatograms and percent mass yield as a function of boiling point for sample fractions from a ROSE\textsuperscript{™} process.\textsuperscript{(14)} In this study, propane was used to extract the deasphalted oil fraction from the petroleum residue.

HTSD has proven valuable for characterizing yield at defined temperatures for heavy feeds and products in the development of technology for upgrading crude and heavy oils. For example, the chromatograms shown
Figure 11 Analysis for resid (a), DAO (b), and asphaltene (c) from the ROSE™ process by using HTSD.

amount of resid and the increase of liquid yield at defined temperatures.

7 CRUDE OIL CHARACTERIZATION

7.1 Yield Correlations between Crude Assay Distillation and High-temperature Simulated Distillation

The crude assay distillation procedure is defined by the methodologies of ASTM Methods D2892 and D5236. The procedure first uses a 15-plate column operating under a reflux ratio of 5:1 (D2892) which, as discussed in section 3.1, is known as TBP distillation. The distillation is usually started at ambient pressure (760mmHg)
and then switched to vacuum conditions (for example, from 100 mmHg and then to 2 mmHg minimum) to extend the method to about 343 °C (650 °F) AEBP. At this point the remaining charge is transferred to a vacuum potstill method (D5236) where the distillation is continued at lower pressure (0.3 and 0.1 mmHg minimum allowed) thus allowing for an AEBP limit of about 538–565 °C (1000–1050 °F). Conversion tables for the vacuum conditions to AEBP are included in the methods.

Although the crude assay distillation (D2892 and D5236) procedure provides only an estimate of the yields of the products of various boiling ranges, the results (when properly and skillfully obtained) are of great importance for the characterization and commercial trading of crudes. However, several areas that can contribute to data variability of the crude assay distillation procedure include:

- the use of two different consecutive distillation methods with widely different characteristics such as efficiency, column hold-up and pressure drop across the column;
- inaccuracies in pressure and temperature readings and the subsequent conversion to AEBP;
- maximum attainable temperatures (AEBP) and cracking limits (maximum liquid temperature tolerance) are different for different types of crudes.

This grouping represented a good range of crudes with widely varying content of pitch, sulfur, nickel, vanadium, oxygen, Conradison Carbon or microcarbon residue, and asphaltene.

The comparisons of the yield curves (expressed in mass percent) of crude assay (ASTM D2892 and D5236) to HTSD were presented for five typical crudes spanning the range of light, intermediate, and heavy API gravities. Each crude was compared at eleven distillation cutpoints (°F): 68, 155, 265, 350, 400, 500, 600, 700, 800, 900, 1000. In another series of comparisons, the percent mass at each of the eleven cutpoints as determined by HTSD was subtracted from the percent mass from crude assay (D2892 and D5236).

The HTSD analysis results of crudes have been compared to crude assay distillation results in a study reported by Villalanti et al.\(^\text{(15)}\) About 100 crudes ranging in API gravity from light to heavy were analyzed. In that study the crudes were grouped into three categories based on API gravity (Table 6) and then plotted against the distillation cutpoints (Figure 13).

Figure 13 Comparison of physical distillation assay and HTSD as % weight difference in their values at each cut point for crude oils grouped by API gravities.
correlation between crude assay distillation and HTSD yield at each cutpoint results in an SD of <2% weight except at the crossover point at 399°C (750°F) (Figure 14).

Advantages cited in that study for characterization of crude by HTSD include:

- method precision;
- faster turnaround and less expense than laboratory physical distillation;
- valuable business tool for evaluating new crudes and confirming crude quality before purchase;
- ensuring crude product integrity during transportation and delivery.

7.2 Crude Oil Contaminants

Product integrity must be verified in the course of crude oil trading. Enormous quantities of crude oil are transported and processed daily. Product adulteration can occur whether intentionally or not. A useful application of HTSD is in monitoring product integrity. For example, the blending of pitch (defined as 538°C+ or 1000°F+) into crudes has been spotted at concentration levels of about 1.5 percent mass and lower.\(^\text{16}\) Advantages of HTSD for this application include speed of analysis, small sample quantity requirement, and extended boiling range of the method.

8 PETROLEUM HYDROCARBONS IN ENVIRONMENTAL SAMPLES

SimDist methods are becoming more widely used in environmental applications. HTSD is useful for characterizing hydrocarbons which can be present as soil and water contaminants; for example, to map and follow hydrocarbon removal processes which may involve biodegradation, thermal, and/or physical separation methods.

8.1 Soil Contaminants

An example of a soil extract analysis by HTSD is shown in Figure 15. For analysis the soil is weighed into a small vial and contacted with a weighed amount of solvent such as carbon disulfide, and the extract is analyzed. To improve sensitivity, samples are prepared for analysis at soil to solvent ratios of about 50 percent mass. Other extraction techniques and solvents can also be used. The HTSD result is useful for characterizing the amounts of material over boiling range regions representative of naphtha, gasoline, diesel, and heavier material. The detectable hydrocarbons can be reported on the basis of percent mass of soil as received or on a normalized percent hydrocarbons.

8.2 Oily Waters

In the HTSD analysis of a predominantly aqueous matrix, the sample is weighed into a small vial and shaken with a weighed amount of solvent, such as carbon disulfide, and the extract analyzed. In this case the extract is the bottom layer because carbon disulfide is denser than water. Water to solvent ratios of about 50% mass are used. Other extraction techniques and solvents can also be used. As with soil samples, the HTSD result is useful for characterizing the amounts of petroleum hydrocarbons in the boiling range of naphtha, gasoline, diesel, and heavier material. The detectable hydrocarbons can be reported on basis of percent mass of sample as received or on a normalized percent hydrocarbon basis.

ACKNOWLEDGMENTS

The authors wish to thank the following colleagues for their valuable contributions to this article: Roby Bearden, Jr, Exxon Research and Development Laboratories,
for his discussions concerning HTSD applications in the FLEXCOR T process; Rinus Daane, Royal Dutch/Shell KSLA, for providing data on the interlaboratory round-robin studies of the HTSD analyses of crude oils; Murugesan Subramanian, Kellogg Brown & Root, for information on HTSD applications in refinery ROSE™ solvent deasphalting operations.

The analysis of hydrocarbon mixtures originating from mineral oil sources using gas chromatography (GC) is compiled in this article and a general overview of GC and detectors, including hyphenated instrumentation, is given. The advantages and limitations of GC, as well as multidimensional GC are described in more detail from a standpoint of process GC, and the historical development of chromatography is put into perspective. Comprehensive tables of target analytes and methods offer access to all standard methods published by the American Society for Testing and Materials (ASTM) for hydrocarbon analysis with GC. Based on these tables, several subtopics are covered: gaseous and liquid hydrocarbons, heteroatom analysis, comprehensive and impurity analysis, natural gases, gasoline and fuel production, polymer feedstocks, hyphenated techniques, and bulk properties.

1 INTRODUCTION

The analysis of hydrocarbons with GC is described in this article. The scope of applications is fairly narrow and covers hydrocarbons originating from mineral oil. This includes products supplied by the refining, petroleum, petrochemical, and oil industry, but not biological samples, environmental applications, food, extraterrestrial sources, etc.

1.1 Hydrocarbons

Hydrocarbons are understood as compounds consisting only of hydrogen and carbon with the general molecular formula C\textsubscript{x}H\textsubscript{y}. In finished petroleum products such as gasoline, it is also of interest to determine fixed gases and hydrocarbons containing sulfur or oxygen. Therefore, a few methods for the analysis of hydrocarbons with these heteroatoms are included as well.

1.2 Gas Chromatography

GC is a technique that separates gaseous mixtures into their components. In many cases, this technique can also be called gas–liquid chromatography: during the separation process, an inert gas (carrier gas, mobile phase) carries the gaseous mixture over a thin layer of an immobilized liquid (stationary phase). As mixture molecules are swept past the liquid film, they briefly permeate the surface and “dissolve” in the liquid before being released again into the gas stream. In essence, an equilibrium exists at any given point between the gas and liquid phase for all components; they are partitioned between the gas and liquid phases. This journey of mixture components takes place inside a tube that is either coated on the inside with a stationary phase (open tubular column), or filled with a grainy powder (support phase) that is coated with the stationary phase (packed column). A stronger affinity of a compound for the stationary phase results in a higher “concentration” in the liquid phase, effectively slowing the migration of this compound relative to the inert mobile phase. With an appropriately chosen stationary phase, most or all mixture constituents
exhibit different partition coefficients. Therefore, the time that these components spend inside the column (retention time) will be different, so that they successively emerge (elute) from the column as separately detectable packets (see Figure 1 for a schematic illustration of column chromatography).

GC does not only deal with mixtures that exist as gases at ambient temperatures, but also for liquid mixtures that can be evaporated at operating temperatures of a gas chromatograph. The evaporation is often carried out during the introduction of a sample onto the column (injection). Elevated temperatures inside the column compartment (oven) are used to turn most or all of the injected sample into a gas. Owing to thermally labile samples or limits of the stationary phase, most GC separations do not exceed 200–300°C. Newer column and oven technology has extended this limit to almost 500°C. At the other end of the temperature spectrum, subambient separations can start as low as −60°C.

1.3 Detection

The great majority of hydrocarbon separations with GC are quantitative in nature, although preparative and qualitative GC exists as well. For the determination of separated components, suitable detectors are employed, mostly universal detectors such as thermoconductivity detectors (TCD) or flame ionization detectors (FID). A TCD is a nondestructive detector suitable for quantitating components in a concentration range of approximately 0.01–100%, while FIDs operate best from the mid parts per billion (ppb, 10⁻⁹) to high parts per million (ppm, 10⁻⁶) range. FIDs exhibit the highest sensitivity for easily combustible compounds such as hydrocarbons. More specialized detectors for sulfur and oxygen as well as multichannel detectors will be introduced in sections 3.6 and 5.1. The continuous monitoring of the column output (effluent) with a detector yields a chromatogram which indicates the separated mixture constituent packets (eluents) as peaks (see bottom of Figure 1).

Sometimes, GC is also used to determine bulk properties such as boiling point distribution or vapor pressure instead of separating individual mixture constituents. In these cases, a chromatogram is evaluated as a whole and the mixture does not have to be separated into individually quantifiable peaks (see section 5.2).

1.4 Advantages

GC instrumentation is robust and a large body of literature and knowledge exists. It is well suited for volatile samples whose constituents can be evaporated at temperatures up to 300°C (sometimes even 450°C). Compared with other instruments, the capital and maintenance costs are low. Using appropriate columns and methods, GC can be highly selective in detecting and determining a wide range of analytes. When hyphenated with multichannel detectors (see section 5.1), GC is used not only for quantitative, but also for qualitative analyses.

1.5 Limitations

Not many sample matrices are suitable for direct (neat) introduction into a GC. Sample cleanup is often required and aqueous samples or salts are frequently detrimental to a GC’s hardware. GC also may not be suitable for the analysis of thermally labile samples. In addition, analytes must be in the gas phase during a split/splitless sample injection and the temperature profile of a separation must be designed to put all analytes into the gas phase. With complex samples, complete separation of all target analytes may require substantial hardware and method development investments, if it can be achieved at all. Potential interferences are difficult to detect if they overlap (co-elute) with the analytes of interest, a problem that can be overcome with multichannel detectors (see section 5.1). Carrier gas must be supplied continuously, which may sometimes be difficult with the most commonly used carrier gases helium (expensive in many parts of the world) and hydrogen (explosion hazards). Duty cycles (times between repeated measurements) for even moderately complex separations (5 min to more than 2 h) may be too long for quick responses based on GC analysis results.

1.6 Process Gas Chromatography

GC-based hydrocarbon analyses\textsuperscript{(7–9)} are usually carried out in the refining, petroleum, and petrochemical industry, where the majority of GCs are used to provide information about the production process. This can be done in an “off-line”, “at-line”, or “on-line” fashion. Table 1 outlines the differences between these approaches.\textsuperscript{(10)} The focus on process applications in hydrocarbon analysis with GCs is also reflected in this article, but many methods developed for on-line analysis can also be applied in the laboratory, and vice versa.

Process gas chromatography (PGC) applications\textsuperscript{(11–13)} can usually be classified into either control, mass balance, or monitoring categories.\textsuperscript{(14)} Control applications usually target a few key components from a single sample stream, require short duty cycles, and the analysis results are used to adjust production parameters. Mass balance applications measure most of the individual components, group the remaining ones, and provide a track record for product quality, content, and process efficiency, e.g. in the determination of the heat value of pipeline gas, which is usually expressed in British thermal units (BTUs; 1 BTU = 1.055 kJ). Monitoring applications are normally designed to meet regulatory requirements, and may obtain samples from a large number of sampling points.

2 HISTORY

The earliest chromatography experiments of Runge, Schönbein, and Goppelsrörder\textsuperscript{(15)} go back to the nineteenth century. However, the invention of column chromatography\textsuperscript{(16,17)} is attributed to Mikhail S. Tswett, who first demonstrated it in 1903.\textsuperscript{(18–20)} When he successfully separated green leaf pigments to study them in their pure state. In a glass column filled with crushed chalk, he separated the leaf alcohol extract into individually identifiable bands of different color. Hence the name “chromatography”, which comes from the Greek words χρωμα (chroma = color) and γραφος (graphos = writing).

Partition chromatography\textsuperscript{(21)} as we know it today, and GC\textsuperscript{(22,23)} in particular, were invented by Martin and Synge in the 1940s and 1950s, ultimately garnering for them the Nobel Prize in chemistry in 1952.\textsuperscript{(24)} Although all separations were initially done on packed columns, open tubular columns are used in the majority of today’s applications.

At the same time GC was developed, mass spectroscopy (MS) began to catch on as a valuable tool for analytical chemists in the early 1950s. The natural fit between these two instruments was discovered soon after that,\textsuperscript{(25)} and the “hyphenation” of MS as a versatile multichannel GC detector turned into today’s widespread usage of gas chromatography/mass spectroscopy (GC/MS). A GC/MS instrument is often used in qualitative GC work to identify unknown mixture components, and also to quantify known constituents. (For other versatile multichannel GC detectors, see section 5.1.)

Just as in other branches of analytical instrumentation, the increasing use of computers for GC has drastically improved productivity, while also increasing the precision and accuracy of separations through hardware control and chromatogram processing. The quantification of analytes – originally done by cutting out peaks from strip-chart recorder paper and weighing them – has progressed beyond integrators with on-the-fly calculations to computers that process entire chromatograms. Computers also make it possible to calculate bulk properties, such as boiling point distribution, vapor pressure, or BTU content by analyzing complete chromatograms.
3 GENERAL METHODS

The analysis of hydrocarbons with GC covers such a vast body of methods that only a few selected applications can be described. This section deals with “general purpose” methods, while more specific problems and their solutions are outlined in sections 4 and 5. There are several organizations that publish standard methods for hydrocarbon analysis, namely the ASTM. The titles and designation numbers of standards published by ASTM pertaining to GC hydrocarbon applications are listed in Table 2. Other organizations for oil, gas, refining, and petroleum, or organizations that publish standards for hydrocarbon analysis with GC are listed in Table 6, and most of the standard titles are accessible and searchable via the Internet.

All ASTM standard methods in Table 2 were examined for target compounds or identified peaks in their reference chromatograms; a complete list of analytes is compiled in Table 3 and common analyte synonyms are show in Table 4. Together, these three tables provide a comprehensive “roadmap” to solve common hydrocarbon analysis problems. Much of the text in the following sections serves as entry points into these tables.

3.1 Multidimensional Gas Chromatography

Common chromatography obstacles such as a wide range of target analytes or long separation times are usually overcome with multidimensional gas chromatography (MDGC). Possible variations for MDGC are almost limitless, but they all share common characteristics: during the separation, part of the sample is diverted from the straight injection → column → detector scheme to traps, vents, other columns, and other detectors. Typical applications of MDGC are multiple columns of different selectivity to cover a wider range of components, rearrangement of elution order to speed up separation, and venting of unwanted compounds to protect analytical columns or to complete a separation in less time. Comprehensive two-dimensional separation with gas chromatography (GC × GC) is another tool in the MDGC toolbox to separate mixtures with hundreds of components from a single injection. With this technique, the effluent from a longer column is re-injected as sample pulses onto a short column, where separation is accomplished about two orders of magnitude faster than in the longer column, resulting in a three-dimensional chromatogram. As the separation in the primary and certainly in the secondary column becomes faster, narrow injection plugs, rapid sample transfer between columns, and miniaturized hardware become more and more critical.

An example of a heartcut and backflush-to-vent MDGC system is shown in Figure 2 and Figure 3. Figure 2 depicts the plumbing arrangement between valves, columns, vents, and detectors, while the flow through the columns is illustrated in Figure 3. This arrangement is used to separate trace amounts of methane and ethane from ethylene, the main constituent. Normally, these components elute in the order CH₄, C₂H₄, and C₂H₆. The separation begins with valves in position 1, stabilizing the flows prior to sample introduction. After the injection with the sample valve (SV), the valves are changed to position 2 (beginning of first heartcut), allowing the methane peak to pass from column 1 through the TCD into column 2. Once the end of the methane peak has been observed with the TCD, the valves are switched back to position 1 (end of first heartcut), which vents the ethylene peak after it emerges from column 1 and the TCD. Once the ethylene elution from column 1 is complete, the valves are switched to position 2 (beginning of second heartcut) to allow ethane (with traces of unseparated ethylene) to flow into column 2 for detection by the FID. Once ethane has completely exited column 1 (end of second heartcut), the valves are switched to position 3, reversing the flow through column 1 and thereby venting all heavier components (backflush to vent), while ethane completes its course through column 2.

3.2 Gaseous Hydrocarbons

Hydrocarbons and related gases that are in their gaseous state at ambient temperature (C₁ through C₅ or C₃) are measured in ASTM standard methods D2504 and D3612 (see also D1945, D1946, D2163, D2426, D2427, D2505, D2593, D2712, and D4424). Measurements in these methods often include fixed gases such as oxygen, nitrogen, and carbon dioxide as well, and are usually applied to natural gas processing or polymer precursor production such as ethylene or propylene.

3.3 Liquid Hydrocarbons

Except for waxes and tars of high molecular weight, most other common hydrocarbons up to about C₂₀ exist as liquids at ambient temperature. The melting and boiling points of n-alkanes are plotted in Figure 4 as reference points. Most ASTM standard methods for liquid hydrocarbon analysis with GC deal with specific applications or target compounds, but there are also several that are of general nature and do not fit into any specific category: D2306, D2597, D3524, D3525, and D5917.

3.4 Impurity Analysis

The characterization of trace components in the production of high purity compounds or in hydrocarbon waste is important to meet customer specifications, avoid catalyst poisoning in polymer production, or to comply

**Figure 2** Plumbing diagram for heartcut and backflush-to-vent arrangement. HC = heartcut, BF = backflush, CV = column valve. (Adapted from Combs and Cook, Figure 4.22. Copyright 1995, Chapman & Hall. Reprinted with kind permission from Kluwer Academic Publishers.)

with environmental regulations. ASTM methods D2360, D3054, D3760, D3797, D3798, D4291, D4735, D5060, and D6229 address impurity analyses of a more general scope. (Methods D2268, D2426, D2505, D2593, D2712, D4492, D4864, D5135, D5441, and D5713 are geared more towards specific applications.)

### 3.5 Comprehensive Analysis

An encompassing analysis of naturally occurring hydrocarbon mixtures and derived products is almost impossible, considering that these mixtures contain hundreds, if not thousands, of closely related compounds. The number of possible isomers for saturated alkanes with the general molecular formula \( C_nH_{2n+2} \) expands rapidly as the carbon number increases.\(^{(32)} \) Between \( C_1 \) and \( C_6 \), there are 13 different isomers, but between \( C_7 \) and \( C_{12} \), this number increases to 651. This does not even take cycloalkanes, olefins, and aromatics into account. A few ASTM methods specialize in analyzing a section of the hydrocarbon spectrum, identifying many of the components in complex mixtures: D5134, D5442, and D5443.

### 3.6 Heteroatom Analysis

During the production of petroleum products, it is frequently necessary to remove sulfur-containing components to minimize the sulfur content of the process output. This in turn reduces the generation of \( SO_2 \) during the combustion of fuels consumed for propulsion, heating, and energy production in power plants. Sulfur is also undesirable in the production of polymers from...
3.7 Specific Compounds

ASTM offers a number of methods that deal with the analysis of specific nontrace target analytes, usually for purity analysis: D2268, D3257, D3606, D4367, D4492, D5135, D5501, D5713, and D5441 (see also D3054, D3760, D3797, D3798, D4291, D4735, D5008, and D5060).

4 ON-LINE APPLICATIONS

A number of hydrocarbon analysis problems are typical applications for PGCs and some of them are outlined in this section. The main differences between laboratory (off-line) and process (on-line) GCs are outlined in Table 1. In addition, PGCs are calibrated almost always externally owing to the difficulty of mixing internal standards into a process stream.

4.1 Natural Gas Analysis

In most cases, the analysis of natural gas with GC is straightforward, including “fixed gases” such as H₂, He, N₂, O₂, CO, and CO₂, which can be detected with a TCD using hydrogen or helium carrier gases. If H₂ and He need to be detected, a nitrogen carrier gas is generally used. ASTM methods D1945, D1946, and D2163 (see also D6228) describe the analysis of natural gases. In some cases, CO or CO₂ may have to be measured at trace levels, where FID detectors are usually employed, but neither of these two analytes can be detected directly with an FID. In order to overcome this limitation, these two components are passed through a methanator that converts them to CH₄, which in turn is easily detectable by an FID.
4.2 Gasoline Blending

Gasoline and other propulsion fuels have to bridge several goals, which sometimes seem to conflict with each other: environmental regulations, which vary from country to country and even from state to state, fuel evaporation rates based on seasonal temperatures, driveability (octane number), consumer prices, compatibility with combustion engines manufactured throughout the twentieth century, different fuel grades, and more. Several parameters such as Reid vapor pressure (RVP), total aromatics, total sulfur, total oxygenates, and total olefins are measured to control and adjust the production process, and a couple of ASTM methods assist in characterizing finished fuel products to ensure consistent quality: D2427, D4420, D4806, D4815, D5580, D5623, D5769, and D6296. There are also a number of other ASTM methods that are not necessarily fuel specific, but may also be needed to analyze additives that are used during the gasoline blending process: D3606, D5441, D5501, D5504, D5541, D5599, D5623, D5769, and D5986.

4.3 Polymer Production Feedstock

A very significant portion of polymer products are manufactured using ethylene, propylene, and other olefin precursors. In most cases, these olefins must meet certain ASTM methods that analyze impurities in ethylene, propylene, and butadiene are D2426, D2505, D2593, D2712, D4424, D4864 (see also D2163 and D5303).

5 OFF-LINE APPLICATIONS

Most on-line applications can also be employed in off-line analyses, and vice versa, but the two application areas outlined below are usually done in a laboratory setting.

5.1 Hyphenated Techniques

Many of the previously discussed GC detectors (TCD, FID, SCD) are single-channel detectors, which means that they provide a single signal for each measured point along a chromatogram. Their simplicity can also lead to problems, when target analyte peaks overlap or merge with interferences, or when unknown components need to be identified. Single-channel detector responses cannot discriminate between closely eluting analytes, and identification based on retention time is risky at best. This problem is usually solved by linking or “hyphenating” GC instruments with general-purpose instruments such as mass spectrometers, which provide an entire spectrum for each measured point along a chromatogram. Most compounds give rise to different mass spectra, so that a computer-based separation of overlapped components or the identification of unknown components becomes possible.

One of the shortcomings of MS, the inability to distinguish between isomers, was recognized as well. Infrared spectroscopy (IRS) overcomes this problem, but it took much longer to develop a practical interface between IRS and GC. Compared with GC/MS, gas chromatography/infrared spectroscopy (GC/IRS) is much less used today because of higher instrumentation cost, lower reliability, and lower sensitivity. This is particularly true for hydrocarbon analysis with GC/IRS. In rare cases, when the analysis of organometallic compounds is necessary, atomic emission spectroscopy (AES) can also be used as a GC detector for general hydrocarbon analysis.

There are many applications for GC/MS and most GC laboratories, if not all of them, use MS in at least one of their GC instruments to maximize the versatility of their analytical capabilities. ASTM defines only one GC/MS method, D5769, for the analysis of finished gasoline. For GC/IRS as a much less widely applied technique, ASTM offers a standard method as well. The GC/IRS method D5986 expands the scope of the GC/MS method D5769 in order to distinguish between isomers such as dimethyl- and trimethylbenzenes.

5.2 Bulk Properties

Chromatograms contain a host of information pertaining not only to the concentration of the sample constituents, but also to so-called “bulk properties” that are not tied to any particular compound, but to the entire mixture. Such properties include BTU values, specific gravity, vapor-to-liquid ratio (V/L), RVP, carbon numbers, and boiling point distribution. In particular, the determination of boiling point distributions with GC (simulated distillation) is of interest in many areas of the petroleum processing industry, because it avoids costly, time-consuming, and error-prone analyses with actual distillation equipment. Simulated distillation with GC is actually quite simple: the system is calibrated with a mixture of hydrocarbons of known boiling points, typically n-alkanes, and several representative aromatics and branched alkanes. During a temperature-programmed separation, the components of the calibration mixture elute at known times and therefore calibrate the time axis as a “temperature axis”. When an actual sample is analyzed, the total chromatogram area is calculated, and then the first n% of this area are correlated to the temperature axis to

a Publishes standard methods for hydrocarbon analysis with GC, titles accessible via the Internet.
b Publishes a number of application notes on the Internet.

obtain “temperature versus percent off” value pairs. ASTM defines several methods for simulated distillation (D2887, D3710, D5307, D5399, and D5480), which have to operate within certain temperature and sample constraints.

ACKNOWLEDGMENTS

I wish to acknowledge Ulrich Gökeler (Siemens AG) and Christopher Schalleur (Honeywell Industrial Automation) for providing me with application notes for systems manufactured by their respective companies. I also wish to thank Bob Bade and Jerry Combs for providing valuable input during the writing of this article.

For reference purposes, major vendors of PGCs are listed in Table 5, and most of them provide some information about their gas chromatographs that go beyond mere advertising. Aside from ASTM, many organizations provide standards or application notes for GC hydrocarbon analysis, and many of them are accessible or searchable on the Internet as well (see Table 6).

1 Introduction

Substances in all states of matter can be used as lubricants provided that they reduce friction and wear between materials in contact.

The majority of lubricants are liquids. They can be classified according to their origin into two main groups: mineral oils derived from petroleum (the majority); and synthetic oils. Most liquid lubricants contain additives to improve their natural properties, or give new properties to them, so they have qualities suitable for their applications and their efficiency may be prolonged.

Mineral lubricating oils are obtained from crude oils: the chemical composition of the crude petroleum has a great influence on obtaining lubricating oils of the required properties. In terms of chemical composition, crude oils are classified into alkanic (or paraffinic) crude oils with more than 50% alkanes, cycloalkanic or cyclic or naphthenic crude oils with more than 50% cycloalkanes, and aromatic crude oils with more than 50% aromatics. Alkanic crude oils are mostly light, wax bearing and of low sulfur content. Cycloalkanic crude oils are often heavy, wax-free or of low wax content and may contain sulfur compounds. In greater detail, the hydrocarbon groups present in the crude oils are straight-chain and branched alkanes, alkylcycloalkanes, alkylaromatics and alkylcycloaromatics.

From a property point of view, comparison of different hydrocarbon classes of the same carbon number shows that straight-chain alkanes (n-alkanes, n-paraffins) have the lowest viscosity, the highest viscosity index, particular, gated spin echo (GASPE) and distortionless enhancement by polarization transfer (DEPT) have been applied to obtain quantitative CH₄ subspectra in petroleum fractions.

Usually the quantitative data obtained from GASPE have a better accuracy than those from DEPT and it will be shown how GASPE is applied to study the molecular characteristics of the aliphatic moieties of base oils of a different nature.

On the basis of the GASPE data and of the average molecular mass obtained via vapor pressure osmometry (VPO), the average number of branches and aliphatic rings can be calculated. Moreover, on the basis of GASPE, the distribution of side chain lengths and the positions of the methyl groups along the straight chain (methyls are the only groups for which the positions are directly obtained from NMR spectra) were obtained.

All these structural features are related to the finished lubricant’s performance in both crankcase and industrial applications.

1 INTRODUCTION
(VI > 200), the lowest evaporation loss and the highest flash point. Their pour point is high (40 °C or more) and in high concentration they are undesirable. Generally they are removed from lubricating oils by solvent dewaxing or catalytic cleavage.

Branched alkanes (isoalkanes, isoparaffins) differ from the n-alkanes by having alkyl substituents on the main chain. If the alkyl side chains are short and not very numerous, the isoalkanes are similar to the n-paraffins. On the contrary, if the alkyls are long and numerous, isoalkanes have a low pour point, a relatively high VI, low volatility and evaporation loss and a high flash point. Such isoalkanes are usually present in small amounts in the conventional mineral oils, but they are predominant in the unconventional oils as those obtained by hydrocracking and hydroisomerization processes (see section 2.3) or manufactured synthetically (polyolefins).

Alkylcycloalkanes (napthenes) of the same carbon number have higher viscosity, lower VI, lower flash point and higher evaporation loss than the alkanes and the isoalkanes, but their pour points are generally lower.

Alkylaromatics are characterized by one or more aromatic rings: aromatic rings have a greater effect than the cycloalkanic ring on the viscosity of lubricating oil cuts and at the same time decrease the VI.

2 BASE OIL MANUFACTURE

2.1 Mineral Oils

The manufacture of lubricating oils from crude oils includes separation, refining and dewaxing processes. The first step is the separation process, which is the distillation of the crude oil to produce gasoline, kerosene, gas oil and an atmospheric residue. The viscous oil cuts are obtained from the atmospheric residue by vacuum distillation. Usually the temperature does not exceed 410 °C. Vacuum distillation is normally used to produce three or four lubricating oil distillates and vacuum asphalt. Lubricating oil distillates differ from one another by distillation range, average molecular weight, viscosity, and flash and pour points. The main criteria used are the viscosity and the flash point.

The second step is the refining, which substantially changes the chemical composition of lubricating oil distillates and can thus control the properties of the distillates. Its primary effect is to reduce the concentration of the most polar constituents of the distillates. The object of this process is to improve color, the VI, and long-term stability. Nowadays the most diffuse refining process is the solvent refining, which consists of separating wax-free oil cuts into two layers: one rich in less-polar components and poor in solvent, called the raffinate layer; the other rich in polar components and solvent, called the extract layer. The most common selective solvents are furfural, which is suitable for all oil stocks, and phenol, which is used more for waxy and heavy cut oils.

The last step is the dewaxing process, which is the dominant process in the recovery of oils of low pour point and good rheological properties at low temperatures from raffinates. The oil is diluted with the solvent, chilled to low temperature and the separated wax crystals are filtered off. Suitable solvents include propane, ethane and the so-called solvent/antisolvent mixtures, such as methyl ethyl ketone (MEK).

The processes described are used for the production of base oils, which are, nowadays, regarded as conventional ones.

2.2 Hydrocracked Base Oils

Although modern types of mineral oils reinforced by additives are capable of covering a broad range of lubricating requirements, their properties are in some cases significantly surpassed by the unconventional base oils, which include hydrocracked oils, wax hydroisomerized oils and polyolefin oils. Hydrocracking of oils consists of the high-pressure hydrogenation of oils by using suitable catalysts. It enables oils to be obtained with a high VI or even an extremely high VI (up to 150). Hydrogenation changes the composition of all homogeneous oil groups: the viscosity, density, sulfur content and aromatic content are all reduced, whereas the VI, hydrogen content, concentration of cycloalkanic compounds and rings are all increased. Hydrocracking enables high-grade and high-VI oils to be produced economically. Oils of this quality cannot be obtained by solvent refining. The superiority of hydrocracked oils is in their very high VI (up to 130), good response to the additives, lower volatility at the same viscosity and lower biological activity. Less conventional characteristics are poorer stability to light, higher corrosiveness after oxidation, and lower solvent power for polar substances, which are generated by oxidation.

The hydrocracked oils are generally solvent dewaxing and, because of this, their pour points are not very low.

2.3 Hydroisomerized Base Oils

More recently, catalysts containing a hydrogenation component on a molecular sieve have been used for wax isomerization. They have permitted the development of a new process for lowering the pour points of high-wax feeds – a once-through process without requiring a solvent dewaxer – and therefore can be used to produce ultrahigh-VI oils with a low pour point. The oils obtained by this process are called wax hydroisomerized oils.
2.4 Polyolefins

The synthetic oils are the highest performance oils. They are termed synthetic because they are not obtained directly from petroleum. In comparison to mineral oil products, synthetic lubricants have the disadvantage of much higher cost. They can be classified into the following categories:

- synthetic hydrocarbons;
- polyether oils;
- esters of carboxylic acids;
- phosphoric acid esters;
- silicon-containing oils;
- halogenated hydrocarbons and halocarbons.

Among these classes of synthetic oils, we consider only the synthetic hydrocarbons because analysis of the others is not general but is specific for each product.

Synthetic hydrocarbons are produced by polymerization of olefins in the presence of Lewis acids (e.g. Al\(_2\)Cl\(_6\), BF\(_3\) and their complexes) or Ziegler catalyst (e.g. Al\((\text{C}_3\text{H}_6)\)\(_3\)Cl and promoters) in the liquid phase. They offer a number of advantages: they have narrow boiling ranges and contain small quantities of unsaturated or polycyclic aromatic compounds and traces of nitrogen-, sulfur-, or oxygen-containing impurities. They have favorable low-temperature characteristics and respond well to additive treatment. Their variable temperature characteristics are good.

In recent years, poly(\(\alpha\)-olefins) have received considerable attention as high-performance functional fluids in a variety of applications. They are manufactured in the presence of Lewis acids by oligomerization of 1-alkenes in the range C\(_8\)–C\(_{12}\), followed by hydrogenation of the double bond: they are almost pure isoalkanes. These poly(\(\alpha\)-olefins) are characterized by high thermal stability, low viscosities even at low temperature, low pour points (down to \(-80^\circ\text{C}\)), high VI (up to 195), high flash point and low volatility. Almost all of the poly(\(\alpha\)-olefins) available today are produced from 1-decene. They can be classified into different grades depending on their 100 °C viscosities.

When selecting the appropriate base oil to use in a formulation, there are a range of properties that can be measured and used to predict performance. Although many of these properties are modified or enhanced by the use of additives, knowledge of the base oil characteristics is vital for effective formulation of any lubricant. The complexity of chemical composition of the base oils requires that most measurements are of bulk physical or chemical properties that indicate the average performance of all the molecular types in the base oil.

The main physical properties are:

- **Viscosity.** This is a measurement of the internal friction within a liquid. It is a vital property of a lubricant because it influences the ability of the oil to form a lubricating film or to minimize friction and reduce wear. The unit of absolute viscosity is the Pascal second (Pa · s), although the centipoise (cP) is often used as an alternative unit (1 Pa · s = 10\(^3\) cP).
- **Viscosity/temperature relationship – VI.** The most frequently used method to compare the variation of viscosity with temperature between different oils is by calculation of a dimensionless number, known as the VI. The higher the VI, the less the effect of temperature on the viscosity of the sample.
- **Low-temperature properties.** When a sample of oil is cooled, its viscosity increases in a predictable manner until wax crystals start to form. The matrix of wax crystals becomes sufficiently dense with further cooling to cause an apparent solidification of the oil, but it has not undergone a true phase change. Many lubricating oils have to be capable of flow at low temperatures and a number of properties should be measured. Cloud point is the temperature at which the first signs of wax formation can be detected. Pour point is the lowest temperature at which the sample of oil can be made to flow by gravity alone.
- **High-temperature properties.** The high-temperature properties of oil are governed by the distillation or boiling range characteristics of the oil. Volatility is important because it is an indication of the tendency of the oil to be lost in service by vaporization. Several methods are used to characterize volatility but the most used is the Noack method, where the sample is heated for 1 h at 250°C and the weight loss is measured. The flash point of an oil is important from a safety point of view because it is the lowest temperature at which autoignition of the vapor occurs.

Various other physical properties may be measured, most of them relating to specialized lubricant applications.

The most important chemical property of base oils is their resistance to thermal–oxidative degradation.

3 BASE OIL PROPERTIES

Lubricants are formulated by blending base oils and additives to meet a series of performance specifications. These specifications relate to the physical properties of the oil when it is new and also ensure that the oil continues to function and protect the engine or machinery in service. Self-evidently, lubricant performance is determined by the base oils and the additives that are used in the formulation.
Although the formulated lubricant may have many desirable properties when new, oxidation can lead to a dramatic loss of performance in service by oxidative reactions. A variety of different stability tests have been devised to measure resistance to oxidation under different conditions.

4 CHEMICAL COMPOSITION

Even if the properties of lubricating oils are largely due to the additives, the importance of the chemical composition of base oils on the finished lubricant performance is increasing more and more and this is particularly true for improved fuel efficiency, which is being driven by both legislation and product specification. This requires a deep knowledge of the molecular characteristics of the base oils, which is not easy because they consist of large numbers of structurally different compounds. A large number of correlations based on the relative distribution of paraffinic-, aromatic- and naphthenic-type hydrocarbons are reported in the literature but these studies do not involve the nature and distribution of the aliphatic moieties, which, vice versa, determine the low-temperature and rheological properties of base stocks. Proton nuclear magnetic resonance (1H-NMR) and 13C-NMR techniques have been used to estimate structural parameters in petroleum cuts but they have limitations in resolving the resonance of CHₙ (n = 0–3) groups in the aliphatic region.

To overcome the problem of signal overlap, some selected multiplet subspectral 13C-NMR analyses were developed and, in particular, GASPE has been applied to obtain quantitative abundances of CHₙ groups in petroleum fractions. Recently GASPE/NMR was used to compare different base oils: mineral, hydrocracked, wax hydrosomerized, poly(a-olefins) and poly(unsaturated olefins). From GASPE spectra the fractional abundances of CHₙ, the number and length of branches, the position of methyl groups along the straight chain and the average number of aliphatic rings were obtained.

5 CONVENTIONAL BASE OIL TESTING AND ANALYSIS

The testing of lubricants is based on chemical and physical properties and on parameters that represent statistical means of the molecular properties. The essential methods have been standardized on an international basis by organizations such as the ASTM; USA, the Institute of Petroleum (IP; UK), the Deutsches Institut fur Normung (DIN; Germany) and the International Organization for Standardization (ISO). Hereafter, the most diffuse tests for analysis of physical properties and hydrocarbon type are summarized:

- **Viscosity.** Kinematic viscosity is measured routinely with ease and great precision in capillary viscometers suspended in constant-temperature baths. Standard methods are ASTM D445 and IP 71, and a number of standard temperatures are used, especially 40°C and 100°C.

- **Viscosity/temperature relationship – VI.** VI are calculated by measuring the kinematic viscosities of the sample at two different temperatures (40°C, 100°C) and comparing the viscosity change with an empirical reference scale. Full definitions of the methods of calculation are given in ASTM or IP manuals (ASTM D2270, IP 226).

- **Low-temperature properties.** The pour points are measured with ASTM D97 and IP 15, in which the oil is warmed and then cooled at a specified rate until the lowest temperature is reached at which the sample can be made to flow by gravity alone.

- **Volatility.** This is important because it is an indication of the tendency of oil to be lost in service by evaporation. Generally it is measured with the Noack method, where the sample is heated for 1 h at 250°C and the weight loss is measured (DIN 51581).

- **Hydrocarbon analysis.** The detailed hydrocarbon analysis is obtained by a two-step procedure. The first step separates the aromatic and saturated fractions by column chromatography (ASTM D2549). The aromatic fraction is then characterized further by mass spectrometry (ASTM D3239) and the saturated subclasses of paraffins and cycloparaffins are measured by a mass spectrometry method (ASTM D2786).

6 MOLECULAR CHARACTERIZATION OF BASE OILS BY NUCLEAR MAGNETIC RESONANCE

NMR is the most important spectroscopic technique available for molecular characterization of the hydrocarbon skeleton. On the basis of the positions and intensities of signals, it is possible to identify the types and number of different nuclei, especially H and C in organic compounds. Some important books describe the fundamentals of this spectroscopy, which is widely used in different fields such as chemistry, physics, medicine and pharmaceutics.

1H- and 13C-NMR techniques have been utilized also for the estimation of structural parameters of low- and higher boiling petroleum cuts. The 1H-NMR spectra of
base oils consist of two main types of signal (Figure 1): a broad resonance at 6.8–8 ppm due to H on aromatic carbons; and signals at 2–0.5 ppm due to H and aliphatic carbons. In the aliphatic regions it is possible to distinguish the H of methyl groups of paraffinic chains at nearly 0.8 ppm and a sharp line at nearly 1.25 ppm due to CH₂ of paraffinic chains.

The ¹³C-NMR spectra of base oils (Figure 2) show the signals due to aromatic carbons between 100 and 150 ppm and those of the aliphatic carbons in the region 0–50 ppm. Particularly in the aliphatic regions there are a great number of peaks due to branched and cycloparaffins: some structural assignments have been proposed but they refer predominantly to the prominent peaks, whereas a great part of the signal is due to the multiplicity of weak resonances spread over the spectral width. The isomeric forms present originate from these latter; for instance, there are over 360,000 noncyclic alkane isomers for C₂₀ alkanes and this number rapidly increases for heavier alkanes. In conventional ¹³C-NMR spectra it is very difficult to resolve the resonances of CHₙ (n = 0–3) in the aliphatic region.

To overcome this problem the GASPE technique has been quite useful because it allows the generation of quantitative CHₙ subspectra. An example of the application of the GASPE technique is shown in Figure 3: the ¹³C-NMR spectrum of the squalane molecule (Figure 3), which is used as a model.
compound for base oil, is divided into three subspectra with the C assignments reported in the figure.

The molecule of squalane has the following \( \text{CH}_n \) groups: \((\text{CH}_3)_8(\text{CH}_2)_{12}(\text{CH})_6\). The respective \( \text{CH}_n \) fractions according to Equation (1):

\[
F(\text{CH}_n) = \frac{I(\text{CH}_n)}{\sum I(\text{CH}_n)}
\]

where \( I(\text{CH}_n) \) is the total intensity of the NMR signals of the \( \text{CH}_n \) group, are: \( F(\text{CH}) = 0.20 \); \( F(\text{CH}_2) = 0.53 \); \( F(\text{CH}_3) = 0.27 \). The \( F(\text{CH}_n) \) fractions calculated from GASPE are: \( F(\text{CH}) = 0.21 \); \( F(\text{CH}_2) = 0.53 \); \( F(\text{CH}_3) = 0.26 \). Comparing the data obtained by GASPE with the real values, the GASPE technique results are very accurate.

We have analyzed a few different types of base oils by GASPE/NMR, and in Table 1 they are summarized using letters to define their nature. In Figure 4 the GASPE/NMR spectra of base oil L, as a general example, are shown.

Another advantage of GASPE spectra is to have the methyl signals without the presence of \( \text{CH}_2 \) signals in the region between 5 and 30 ppm. The methyl signals can be assigned to specific branching sites along the hydrocarbon chain. An example of the methyl region of the GASPE spectrum is shown in Figure 5. The main signals of methyl groups are assigned to the hydrocarbon branches shown in Table 2.

Figure 4 Conventional \(^{13}\text{C}-\text{NMR} \) (bottom) spectrum of base oil F (aliphatic region). The GASPE subspectra are labeled according to the component resonance types as C, \( \text{CH}_2 \), and \( \text{CH} + \text{CH}_3 \).

Figure 5 GASPE \(^{13}\text{C}-\text{NMR} \) subspectra of base oil F as a general example.

On the basis of GASPE data, some molecular features have been calculated relating to the number of branches \((\text{NB})\) and the number of aliphatic rings \((\text{NAR})\) for an average molecule. From GASPE spectra the molar fractions of the \( \text{CH}_n \) \((n = 0–3)\) aliphatic group are obtained using Equation (1). The average number of branches is estimated by multiplying the molar fraction of methyls, \( F(\text{CH}_3) \), by the average number of carbons \( (N_C) \) of the base oil, obtained by VPO, which gives the average
number of methyls per molecule, and then subtracting two from the resulting product (the two terminal methyls of the straight chain). The expression is as shown in Equation (2):

\[ NB = nCH_3 - 2 = F(CH_3)N_C - 2 \quad (2) \]

The number of aliphatic rings can be calculated according to Equation (3):

\[ NAR = 0.5N_C[2F(C) + F(CH) - F(CH_3)] + 1 \quad (3) \]

Other molecular characteristics are obtained directly from the NMR spectra: for instance, the molar fractions of aromatic hydrogens and carbons are calculated using Equation (4):

\[ F(H_{ar}) = \frac{I(H_{ar})}{\sum_n I(H_n)} \quad F(C_{ar}) = \frac{I(C_{ar})}{\sum_n I(C_n)} \quad (4) \]

where the denominators are the sum of all spectral intensities of the relative nuclei. In Table 3 the molecular features of the 17 base oils of Table 1 are shown, with the acronyms used in the text.

In Table 4 the molar fractions of different methyl groups with the identification numbers reported in Table 2, are shown. The hydrocarbon-type analysis of each base oil was carried out with gas chromatography/mass spectrometry (ASTM D2549, ASTM D3239 and ASTM D2786). The volume percentages of isoparaffins, cycloparaffins and aromatic compounds are reported in Table 4 the molar percentages of methyl groups on different branches, numbered as in Table 2.

in Table 5, and the physical and rheological properties of the same analyzed base oils are reported in Table 6.

From the analysis of Tables 1–5 it is evident that the molecular features are peculiar to different classes of base oils. For instance, the SR mineral base oils have a greater content of aromatics (vol.% and their H and C fractions), whereas the polyolefins have a greater fraction of methyls on long aliphatic chains (identification number 6 in Table 2). These chemical features certainly influence the physical properties of the base oils: for instance, the higher value of aromatics in SR mineral oils is the cause of their higher pour points, whereas the presence of long chains in the polyolefins should be the cause of their excellent pour points. Some correlation could be tried between performance and molecular feature with statistical models, but at the moment they suffer from the limitations of the low number of significantly different base oils with respect to the large quantity of molecular characteristics shown by these complex compounds. Certainly the possibility of having predictive models of the performance of finished oils based on the molecular characteristics of base oils could represent a very valid tool for lubricant manufacturer choice, especially for the formulation of lubricants with very high performance.

ACKNOWLEDGMENTS

The author is particularly grateful to ENI Group S.p.A and Agip Petroli S.p.A for financial support of his work on lubricants, to Dr Carlo Corno for helpful discussions and suggestions and to Mr Walter Stringo for his technical contribution.

Lubricant Base Oils: Analysis and Characterization of

Arnold L. Shugarman
76 Lubricants Company, Santa Ana, CA, USA

1 INTRODUCTION

Base oils are refined from crude oil, re-refined from used oil, or manufactured to give products with specific chemical and physical properties. Mineral oils are base oils produced from the atmospheric residuum of crude oil. The residua are processed to remove aromatics and nitrogen-, sulfur-, and oxygen-containing compounds which degrade the performance of the finished base oil. Mineral base oils are classified by the molecular type that predominates (paraffinic, naphthenic, or aromatic) and their physical and chemical properties.

Paraffinic base oils tend to have high pour points and must be dewaxed to produce a base oil with acceptable flow properties at low temperatures. Naphthenic base oils have a naturally low wax content and generally have better solvency properties than paraffinic stocks. However, they tend to oxidize more readily than paraffinic oils. Aromatic stocks are valued for their solvency properties rather than their lubricating quality, and are used as process oils in the rubber and printing ink industries. Typical properties of paraffinic, naphthenic, and aromatic oils are shown in Table 1.1)

High-quality re-refined base oils are processed to be indistinguishable from virgin mineral oils derived from crude oil. They are derived from contaminated used oils from a variety of sources. Analyses of re-refined base oils may include tests for contaminants in used oil that are not found in virgin base oils. (Refer to the appropriate American Society for Testing and Materials (ASTM) standard.2) Unless stated otherwise, all references to ASTM methods are from the Annual Book of ASTM Standards, Vol. 05.)

The most commonly used synthetic base oils fall into one of five classes: olefin oligomers, especially polyalphaolefins (PAOs),3,4) esters (dibasic and polyol), alkylated aromatics, polyalkylene glycols, and metalloorganic oligomers (phosphate or silicate esters, siloxanes).5) Chlorine and/or fluorine-substituted hydrocarbons or polyethers are specialty lubricants used where extreme operating conditions are encountered.

Several general references on base oil technology, applications, and characterization have been published and are widely available. Neale has edited a tribology handbook with an excellent review of base oil types and their properties.6) Klaus and Tewksbury provide a comprehensive review of base oil and finished lubricant properties.7) The ASTM has published a monograph on testing petroleum products following ASTM methods8) and an educational guide on base oil characterization tests which covers lubricant performance and safe handling, composition, performance, and consistency.2)

2 BASE OIL REFINING PROCESSES

Base oils are traditionally made by solvent refining to physically extract undesirable aromatics and heteroatomic compounds from the feed, solvent-assisted wax crystallization (paraffinic crudes), and clay treatment to decolorize and stabilize the finished product. In more modern processes, some refiners have replaced solvent refining with hydrotreating or severe hydrotreating, solvent dewaxing with catalytic dewaxing or wax isomerization, and clay treatment with hydrofinishing. Mineral base oils with properties approaching those of PAOs have been manufactured by isomerizing wax derived from slack wax or Fischer–Tropsch synthesis. Base oils produced from vacuum distillates are called neutral oils; bright stocks are base oils refined from vacuum.

3 BASE OIL COMPOSITION

Base oil characterization is important for understanding the relationship between composition and performance of finished products in end-use applications. Rig or engine tests, developed to predict field performance, are often expensive or take a long time to complete. Consequently, a need exists for relatively simple, low-cost tests to predict the performance of a finished lubricant in the customer’s equipment.

3.1 Hydrocarbon Type Analysis

Base oils derived from petroleum are complex mixtures of thousands of individual compounds. To better understand how base oil molecular structure, composition, and properties relate to product performance, investigators have examined individual model compounds and characterized the bulk molecular hydrocarbon types in base oils. Over a 26-year period, American Petroleum Institute (API) sponsored a program to measure the properties of 321 high-molecular-weight hydrocarbons. Briant has provided a thorough analysis of these and other data on model compounds.

ASTM has published several test methods to obtain information on the composition of base oils. ASTM D 2140 and D 3238 give calculated values for the carbon number distribution among aromatic, naphthenic, and paraffinic compounds based on viscosity (ASTM D 445).
density/specific gravity (ASTM D 1481), and refractive index (ASTM D 1218). ASTM D 3238, also known as the refractive index–density–molecular weight ($n_d - M$) method, gives similar, though not identical, results to ASTM D 2140.

More detailed base oil compositional information can be obtained by first separating base oil into aromatic and non-aromatic fractions on a chromatographic column and analyzing each fraction separately by mass spectrometry (MS). ASTM D 2549 describes a chromatographic procedure for separating hydrocarbon mixtures boiling between 232°C and 538°C on a packed column. The non-aromatics fraction is subjected to analysis by high ionizing voltage MS (ASTM D 2786) to give composition by seven saturated hydrocarbon types and one aromatic type. The aromatics fraction is analyzed by high ionizing voltage, low-resolution MS.

ASTM D 2007 (Clay-gel Analysis) and a technique developed by Hirsch et al.\(^{18}\) are column chromatographic procedures used to separate high-boiling petroleum fractions into saturated, aromatic, and polar compounds. Barman\(^{19}\) showed that ASTM D 2007 is subject to cross-contamination of these hydrocarbon classes. Thin-layer chromatography (TLC) with flame ionization detection (FID) is more rapid and accurate. Mohindroo and Preston\(^{20}\) used supercritical-fluid chromatography (SFC) with flame ionization and ultraviolet (UV) detectors to separate base oils into saturates, polars, monoaromatics, and polyaromatic aromatics. Hsu et al.\(^{21}\) developed a rapid, preparative scale, high-pressure liquid chromatography (LC) procedure to separate base oils into compound groups using two columns and solvents of different polarity.

Thermal diffusion allows separation of hydrocarbons by molecular size under the influence of a thermal gradient. Cyclic and linear molecules diffuse by convection towards opposite ends of the apparatus. The process is time-consuming, but it provides detailed information not available by bulk chromatographic separation.\(^{22}\)

Chromatography separates compounds into distinct molecular types but provides no quantitative information on the number of aromatic and paraffinic carbon or hydrogen atoms in each fraction. Nuclear magnetic resonance (NMR) and infrared (IR) analyses provide this information directly. ASTM D 5292 describes an NMR method to measure the mole or mass percent of aromatic carbon or aromatic hydrogen atoms in a sample. A. van de Ven et al.\(^{23}\) developed an improved correlation between $^{13}$C NMR and IR analysis using the aromatic bands at 1610 cm\(^{-1}\) and 815 cm\(^{-1}\) to quantify the mole percent aromatic carbon in a base oil.

UV absorption (ASTM D 2008) is used to detect total aromatics in a sample, especially in severely hydrossythesized base oils, waxes, and white oils where the aromatics content is low. In ASTM D 2269, aromatics are concentrated before UV analysis by dimethylsulfoxide (DMSO) extraction. Similar procedures have been developed to assess the potential carcinogenicity of base oils and aromatic extract distillates.\(^{24,25}\)

### 3.2 Elemental Analysis

Compounds containing nitrogen, oxygen, and sulfur in base oils can have profound effects on the properties and performance of finished lubricants. Elemental analyses are conducted to detect base oil contamination or impurities which survive the process of re-refining used oils. ASTM D 6074 provides a comprehensive list of tests to characterize hydrocarbon base oils (mineral oils) including those for elemental analysis. Sieber and Salmon\(^{26}\) give an excellent summary of the instrumentation and methodology for spectrometric methods of lube oil analysis.

### 4 PHYSICAL AND CHEMICAL PROPERTIES

Physical and chemical properties of base oils can be related, ultimately, to their bulk or molecular properties. Physical property tests are used for manufacturing process control, QC, QA, consistency of finished products, and to set specifications between buyer and seller.

#### 4.1 Viscosity

Viscosity is the critical factor in establishing hydrodynamic or full-film lubrication which reduces friction and wear between moving parts. Viscosity is defined as the ratio of shear stress to shear rate and measures resistance to flow. Newtonian fluids, including base oils above the cloud point, obey this equation. Klaus and Tewksbury,\(^{7}\) Briant et al.,\(^{27}\) and Alexander\(^{28}\) provide detailed descriptions of rheology theory and applications to lubricants.

Dynamic, or absolute, viscosities are most often measured in coaxial-cylinder viscometers.\(^{29}\) Kinematic viscosities are determined by ASTM D 445 which measures the time for a liquid to move through a narrow capillary segment. Absolute viscosity in millipascal-sec. or centipoise (cP) equals kinematic viscosity in mm\(^2\)s\(^{-1}\) or centistokes (cSt) times density (g cm\(^{-3}\)). Viscosities are typically reported at two temperatures, 40°C and 100°C, and a property defined as the viscosity index (VI) is calculated from the values (ASTM D 2270). High VI oils exhibit a relatively small change in viscosity with temperature. Aliphatic paraffins predominate in high VI oils (Table 1). ASTM D 341 describes a procedure and conditions to calculate the viscosity at one temperature from viscosities measured at two other temperatures.

(a) Federal Stable Pour Test (FED-STD-791, Method 203), Naval Publications and Forms Center, Philadelphia, PA 19120, USA; SAE J-300, Appendix B, Society of Automotive Engineers, Warrendale, PA 15096, USA.

Viscosity also changes with respect to pressure, but the effect is much smaller than the temperature effect. Viscosity-pressure relationships are important in highly loaded contacts in gears or rolling element bearings, where the pressures under elastohydrodynamic lubrication can exceed 345 MPa (50 000 psi). Viscosity as a function of pressure can be measured in falling-weight viscometers, capillary viscometers, vibrating-crystal viscometers, and optical viscometers. The effect of pressure on viscosity decreases in the order naphthenics > paraffinics > esters.

Apparent viscosities of non-Newtonian fluids vary with shear rate and shear stress. These include base oils below the cloud point and fully formulated lubricants containing high-molecular-weight components (VI improvers). For engine oils, high-temperature–high-shear viscosity at 150°C and 10⁶ s⁻¹ shear rate represents lubrication conditions in high-speed bearings. Methods to measure viscosity under these conditions include the Tapered-bearing Simulator (ASTM D 4683), Tapered-plug Viscometer (ASTM D 4741), and Multicell Capillary Viscometer (ASTM D 5481).

The Cold-cranking Simulator (CCS) (ASTM D 5293) measures low-temperature base oil viscosities at 10⁴–10⁵ s⁻¹ shear rates. Wax-related viscosity effects are minimized, and measured viscosities are similar to extrapolated viscosities from data obtained above the cloud point. CCS viscosities of fully formulated engine oils correlate with low-temperature engine startup.

4.2 Wax-related Properties

As paraffinic base oils are cooled, wax crystals grow and form interlocking networks throughout the fluid which eventually stop oil flow at low shear rates. The shear stress required to break down the wax structure and resume lubricant flow is called the yield stress. Several tests have been developed to measure low-temperature, engine oil viscosities at low shear and low shear stress after long cooling cycles. Test conditions mimic, but don’t necessarily duplicate, conditions that can cause low-temperature engine oil pumpability failures in the field. Except for the cloud- and pour-point tests, methods listed in Table 2 were developed specifically for fully formulated engine oils.

4.3 Volatility

Base oil volatility is an important factor in crankcase oil consumption, especially at high engine temperatures. Volatility decreases as VI increases for a given viscosity base oil and distillation cut width.

Volatility is measured by an evaporative-loss test (Noack) or gas chromatography (GC) (simulated distillation). In the Noack test, the weight of oil evaporated at 250°C in one hour in flowing air is measured. Variations of the Noack test exist as Coordinating European Council (CEC) L-40-T-87, Japanese Petroleum Institute (JPI)-5S-41-93, Method B, and ASTM D 5800. An alternative apparatus has been proposed which eliminates use of toxic Woods metal as the heat-transfer medium and allows nearly quantitative collection of the volatiles for further analysis.

ASTM D 2887 measures boiling-point distribution for hydrocarbons boiling between 55°C and 538°C. ASTM D 5480 uses an internal standard and was developed specifically to measure volatility of engine oils. Noack volatility is typically 5–15% higher than ASTM D 2887. Choi and Deane showed that two base oils with the same Noack volatility could have different volatilities by ASTM D 2887, and vice versa. Engine oil volatility at high engine operating temperatures appears to correlate better with Noack volatility.

4.4 Other Properties

ASTM D 6074 summarizes the tests used most often to characterize base oils and finished oils. ASTM D 6158 lists the specific tests and specifications for mineral hydraulic oils, including noncompounded base oils. Klaus and Tewksbury and Godfrey and Herguth describe base oil properties from a more fundamental viewpoint and
provide typical properties for different chemical classes of lubricants. The Annual Book of ASTM Standards, Volume 05, describes over 150 test procedures useful for testing or characterizing base oils.

Base oil characterization involves testing and assessment of appearance, viscometrics, safety, interfacial properties, solvency, oxidation and thermal stability, seal compatibility, and volatility. Appearance is determined by color (ASTM D 1500), cleanliness (International Organization for Standardization (ISO) 4406), and clarity (ASTM D 4860). Water above 80–100 ppm, for example, will impart a haze to base oils at room temperature. Color stability can be estimated by light irradiation, either by UV source or sunlight. Mills and Melchior [36] showed that color instability is due to nitrogen and sulfur heterocyclic compounds in base oils. Safety aspects include flash point (ASTM D 92/93) and toxicity (sections 6 and 7). Flash point is a rough measure of volatility and is used to detect low-boiling contaminants in base oils.

Interfacial properties between water and lube oil determine the demulsibility or the speed and efficiency of separating a mixture of the two (ASTM D 2711). Gas release (ASTM D 3827) and foaming tendency (ASTM D 892/6082) relate to the interfacial properties between base oils and gases. Copper corrosion (ASTM D 130) indicates presence of reactive sulfur compounds in base oils.

Solvency for additives and seal compatibility are governed by the chemical composition of base oils. Highly paraffinic base oils (hydrocracked mineral base oils and PAO) tend to shrink rubber seal materials and have lower solubility for additives than mineral oils containing aromatics and napthenes, or synthetic base oils containing esters. Aniline point (ASTM D 611) is a useful guide to mineral base oil aromaticity and solvency properties. The effect of base oils and formulated lubricants on seal materials is determined by methods ASTM D 412/471/2240 [37] and 5662.

5 EFFECT OF BASE OIL COMPOSITION ON LUBRICANT PERFORMANCE

Bench and rig test studies of base oils and formulated lubricants are used as guides to performance of fully formulated oils in field applications. The goal is to reduce the testing cost and maintain a high confidence level of performance when one base oil is substituted for another in a fully formulated lubricant. Hsu [38] conducted a thorough review of bench tests used to correlate performance of crankcase oils.

5.1 Oxidation Tests

Base oil oxidation tests can be classified as oxygen diffusion-limited (bulk), or reaction rate-controlled (thin film). Tests are run with or without catalyst activator. Catalysts simulate surfaces or contaminants that might accelerate oxidation. Oxidation-test results on uninhibited oils can be misleading. Highly paraffinic oils with low sulfur and nitrogen content oxidize more readily than base oils containing sulfur and aromatics, but are more stable with added oxidation inhibitor [39].

Bulk oil oxidation tests include the oxidation test for turbine oils (The Institute of Petroleum (IP) 114), turbine oil stability test (ASTM D 943/4310/IP 157), rotary bomb oxidation test (ASTM D 2272), corrosiveness and oxidation stability of highly refined oils (ASTM D 4636/FTM 791-5308), and the universal oxidation/thermal stability test (ASTM D 4871/5846). Except for the rotary bomb test, which is conducted in a pressurized vessel, oxidation stability is evaluated at atmospheric pressure in flowing air.

Hsu and Cummings [40] developed a thin-film, thermogravimetric analysis (TGA) test to determine oxidation, volatility and extent of polymerization of base oils. Yoshida, Stipanovic et al. [41] used high-pressure differential scanning calorimetry (DSC) to measure base oil oxidative stability and correlated results with ASTM D 943. Klaus et al. [42] developed the Penn State Micro-oxidation Test to evaluate oxidative and thermal stability of base oils, and correlate lubricant degradation processes with those observed in automotive and diesel engine tests. Lubricant is oxidized in a thin film. Residues are analyzed by gel permeation chromatography (GPC). Selby [43] recommended the thin-film oxygen uptake test (TFOUT), ASTM D 4742, to determine base oil consistency and quality.

5.2 Correlation of Base oil Composition and Lubricant Performance

As a general rule, base oil oxidation stability increases with increasing saturates content, and sulfur compounds are beneficial at high temperatures in uninhibited oils or when inhibitors have been depleted [44]. Murray et al. [45] concluded that the relationship between VI and oxidation of solvent-refined base oils held only for base oils from the same crude source and refining process. Robson [46] found that oxidation of lubricants formulated with hydrocracked base oils correlated inversely with aromatics content. Sulfur did not correlate at the low levels found in the hydroprocessed lubes. Stipanovic et al. [41] used base oil compositional analysis, physical property measurements, and engine test results to develop predictive models based on partial least squares (PLS) and neural networks analyses. Multi-ring naphthene and polyaromatic compounds, thioaromatics, basic nitrogen compounds, and “resins” increase oxidation, thermal decomposition, and deposit formation. Supp et al. [47] also found that base oil sulfur increased sludge formation in
the Sequence VE test, but noted that aromatics, especially highly polar base oil components, were beneficial, possibly because they solubilize sludge precursors.

6 TOXICOLOGY

Crude oil atmospheric residua contain polynuclear aromatic, nitrogen-, and sulfur-heterocyclic compounds, some of which may be carcinogenic. While base oil refining removes some or all of these materials, the manufacturer is still responsible for assuring that the final products are non-carcinogenic. Blackburn has reviewed the subject, and background information on test procedures and legal definitions of carcinogenicity are discussed in ASTM D 6074.

Mouse-skin bioassay is the most recognized, direct method for predicting the carcinogenicity of base oils. The time of tumor development and the percentage of animals developing tumors relative to the controls are used to assess carcinogenicity. A bioassay test and DMSO extraction tests have been developed to predict the results of mouse-painting tests to reduce the time and cost to assess carcinogenicity. The Mutagenicity Index (Modified Ames Test), ASTM E1687, is a short-term, microbiological, salmonella mutagenesis assay developed to detect mutagens in base oils. The correlation of mutagenicity and carcinogenicity with PNA content is defined for oils with viscosities >18 cSt at 40 °C, distilling between 250–550 °C. A new test to predict base oil carcinogenicity, DNA adduct formation, is now available.

Method IP 346 specifies DMSO extraction of polycyclic aromatics and condensed-ring polar compounds in virgin base oil and measurement of the polycyclic aromatics in the extract. The scope and limitations are described in the CONCAWE review and the European Union Dangerous Substances Directive. Haas et al. developed another DMSO extraction procedure which is similar to ASTM D 2269. The index they developed includes both PNA content and viscosity to predict results from mouse-painting studies.

7 ENVIRONMENTAL IMPACT OF BASE OILS

Environmental impact is assessed by estimating the ecotoxicity and biodegradation of lubricants. Biodegradation is the oxidative decomposition of carbon, hydrogen, and oxygen compounds by microorganisms. Ecotoxicity is the tendency of a material to negatively impact nonhuman organisms.

The general order of biodegradation of base oils is vegetable oils > synthetic esters > mineral oils ~ alkylenebenzenes > polyalkylene Glycols > PAOs. The relative order depends on the test conditions and method of reporting. Within a family group, lower-molecular-weight compounds degrade faster and more completely than higher-molecular-weight materials.

Biodegradation processes follow two paths. “Ultimate” biodegradation leads to complete biochemical oxidation to carbon dioxide, water, and inorganic salts. “Bioaccumulation” or “primary biodegradation” is a process in which the original molecule is partially degraded and incorporated into a microorganism as biomass. “Primary biodegradation” is followed by monitoring the disappearance of the original substance, while ultimate biodegradation is measured by carbon dioxide production or oxygen consumption.

ASTM D 6046 is a standard classification of hydraulic fluids for their environmental impact. While the document pertains specifically to the biodegradability and acute aquatic toxicity of hydraulic fluids, the methodology and test procedures identified also apply to base oils. ASTM published a companion document, ASTM D 6081, which covers standard practices for aquatic toxicity testing of lubricants and their components. Voltz et al. and Kiovsky et al. reviewed lubricant biodegradation test methods, and provided comparative test data on base oils and fully formulated oils.

The complex chemistry and chemical engineering of fossil fuel materials including petroleums, coal-derived liquids, tar sands, shale oils, refinery streams and refined products can often be adequately simplified by expressing the composition of these materials in terms of group types. Group (chemical) types are series of homologous compounds that exhibit similar chemical properties and a regular gradation of physical properties. A homologous series of compounds, the members of which are termed homologs, contains compounds in which successive members exhibit the same difference in chemical formula with the homologous unit of present interest being CH2. Mass spectrometry (MS) is an ideal, extensively used technique in analyzing for chemical types in terms either of the total amounts of the various homologous series of compounds present in a sample or of the individual members (homologs) of the various series of homologous compounds present in a sample. The focus of this article is the fundamentals of homolog-type analysis because analyses expressed in terms of the amounts of individual homologs rather than in terms of the total amounts of group types benefits the understanding/prediction of the effect of experimental conditions on feedstock production/transportation, product distributions in feedstock refining, end-product quality and environmental impacts. A homolog-type analysis also permits the determination/prediction of chemical/physical properties of a sample that can be expressed as a function of composition; examples being reaction rates, distillation curves and elemental analyses. The discussion of techniques for obtaining the “molecular ion mass spectra” required to produce homolog-type analyses focuses on the use of all glass heated inlet systems (AGHIS) and direct probes for sample introduction, low-voltage electrons for ion formation, and double focusing magnetic sector (DF) and Fourier transform ion cyclotron.
resonance (FTICR) mass analyzers to resolve isobaric ions.

1 INTRODUCTION

The complex chemistry and chemical engineering of fossil fuel feedstocks including petroleums, coal-derived liquids and tar sands and shale oils, refinery streams and refined products can often be adequately simplified by expressing the composition of these materials in terms of series of compounds that exhibit similar chemical properties and a regular gradation of physical properties. Such series of compounds have historically been termed group types. However, the phrases “group-type” and “chemical-type” are taken to be synonyms throughout this article. The concept of homology is implicit in this approach to formulating such analyses. A homologous series of compounds, the members of which are termed homologs, contains compounds in which successive members exhibit the same difference in chemical formula.

Mass spectrometric methods for performing chemical-type analyses can be classified according to whether the analytical results are expressed in terms of the total amounts of the various homologous series of compounds present in a sample or the individual members (homologs) of the various series of homologous compounds present in a sample. The extensive literature devoted to the development and applications of mass spectrometric techniques for performing such analyses over the past 50 years testifies to their extensive use in the fossil fuel industry. The intent of the literature cited here is to provide those who are new to the field with an introduction to the fundamentals of homolog-type analysis. The author apologizes to any of his colleagues whose work was not cited.

This article focuses on the fundamentals of homolog-type analysis for a number of reasons. High-resolution mass spectrometric (HRMS) methods are generic in terms of analyzing for chemical types whereas low-resolution methods necessarily assume that the group types comprising the sample are known. Analyses expressed in terms of the amounts of individual homologs rather than in terms of the total numbers of group types clearly benefits the understanding/prediction of the effect of changes in experimental conditions on chemical and physical processes affecting issues such as corrosion, product distributions, end-product quality and environmental impact. Finally, a homolog-type analysis permits prediction of any chemical or physical property of a sample that can be expressed as function of composition. Examples include the calculation of reaction rates, mass balances, average molecular weights for each chemical type and for the sample, the distillation characteristics for each group type and for the sample and elemental analyses for the predicted distillate cuts and the total sample. The discussion of techniques for obtaining “molecular ion mass spectra” focuses on the use of AGHIS and direct probes for sample introduction, low-voltage electrons for ion formation, and DF magnetic sector and FTICR mass analyzers to resolve isobaric ions. Topics considered in processing these spectra include the assignment of formulas to ion masses obtained from the conversion of time centroids and frequencies in mass spectra acquired using DF and FTICR instruments, respectively, the generation of quantitative distributions from molecular-ion abundances and the calculation of chemical/physical properties from these distributions. In writing this article the author hopes to accomplish in part the goals of providing the individual who is new to the field with an introduction to the fundamentals of HRMS homolog analysis and with an indication of issues in these methods that need to be addressed and resolved.

2 GROUP (CHEMICAL) TYPES

2.1 Definition and Significance in Terms of the Concept of Homology

As noted above, compounds that differ in composition by CH₂, undergo similar chemical reactions and exhibit a regular gradation of physical properties under specific experimental conditions constitute a group or compound type. A chemical (group)-type is a homologous series of neutral or ionic substances. However, as discussed in section 2.3 a homologous series may contain more than one group type. Isomers differ in structure but not in formula and, hence, are subsets in a set of homologous substances. For example, benzene (C₆H₆), and benzene substituted with alkyl groups containing 1, 2, 3, 4, . . ., carbons differ in composition by CH₂ and, hence, correspond to a homologous series of compounds. The ionization of these compounds in a mass spectrometer produces a homologous series of molecular ions. Furthermore, isomers are subsets of homologs of benzene containing two or more alkyl carbons. For example, the third homolog in the series (C₈H₁₆) may reflect the presence of one or more of the four possible isomers, ethylbenzene and o-, m-, and p-xylene. It should be noted that neutral and, hence, ionic homologs consist of compounds and ions containing the various isotopes of their constituent elements.
2.2 Mass Spectrometric Nomenclature: the Specific Z Series Concept

2.2.1 Naming Homologous Series

A homolog-type analysis is synonymous with the identification of the homologous compounds which constitute a sample. Unfortunately, the existence of isomers can complicate to varying degrees the nomenclature for these series. For example, benzene and benzene substituted with one or more alkyl groups may unambiguously be referred to as the benzene series with the number of alkyl carbons possessed by each homolog specified numerically. Thus, the name C-2 alkylbenzenes encompasses ethylbenzene and the isomeric dimethylbenzenes. However, in many instances the existence of isomers makes this approach to nomenclature quite cumbersome. As an example, consider a homologous series of hydrocarbons containing the same number of carbons. If the series either contains or is believed to contain hydrocarbons such as (1) and (2), indenes substituted with one alkenyl group such as (3) and naphthenoindenes such as (4) and the alkylated homologs of these hydrocarbons are isomers of alkylated naphthalenes containing the same number of hydrogens. If the series either contains or is believed to contain hydrocarbons such as (1) and (2) and their alkylated homologs in addition to naphthalenes then the series could be and often is referred to as the naphthalene/trinaphthenobenzene series. The possible presence of hydrocarbons such as (3) and (4), isomers of these compounds and their alkylated homologs would require that the series be called the naphthalene/trinaphthenobenzene/alkenylindene/naphthenoindene series. Such difficulties in nomenclature are circumvented by using the Z-series concept to classify molecular ions and, hence, their precursor compounds according to the homologous series to which they belong.

2.2.2 Specific Z Value

The vast majority of organic compounds in petroleums, synthetic crudes, refinery streams and materials derived from their processing are derived from the combination of two or more of the elements carbon, hydrogen, nitrogen, oxygen and sulfur in various proportions by weight. Petroleums and syncrudes also contain varying amounts of organic compounds substituted with metallic elements such as nickel, vanadium and iron. The general formula of organic and organometallic compounds of present interest is \( C_nH_{2n}O_{a}S_bNi_cV_dFe_e \). Homologs differ in composition by \( 1, 2, 3, 4, \ldots n \), CH\(_2\) groups. Therefore, we associate \( 2n \) of the \( x \) hydrogens in the general formula with the \( n \) carbons leaving \( x-2n \) hydrogens. Thus, the general formula becomes \((CH_2)_nH_{2-2n}N_0O_{a}S_bNi_cV_dFe_e\). Homologs have the same value of the quantity \( x-2n \). This difference is defined as the specific Z value as shown in Equation (1)\

\[
Z = (x - 2n)(N_0O_{a}S_bNi_cV_dFe_e)
\]  

(1)

As seen in Equation (1), a homologous series is designated by the numerical value of \( Z \) followed by the symbols for and the numbers of the heteroelements that are present. The symbol H is used for designating hydrocarbons because all elemental coefficients other than those for carbon and hydrogen are zero. Thus, the general formula for compounds and ions of present interest may be written as \((CH_2)_nH_{2-2n}N_{a}O_{b}S_{c}Ni_{d}V_{e}Fe_{f}\).

Compounds and ions of present interest may be viewed as being derived from combinations of basic structural groups. Table 1 lists specific Z values for a number of these structural groups. Thus, the specific Z value for any species considered as being derived from these structural groups species is given by\

\[
Z = \sum_{i} \alpha_i Z(X_i)
\]

Figure 1 Examples illustrating the specific Z series concept, prediction of Z values for species from Z values of functional groups and relation between Z values and rings plus double/triple bonds.

where \( a_i \) is the number of the \( i \)th structural group in the structure. From Table 1 and Equation (2) it follows that the number of rings plus double/triple bonds present in a species is

\[
R = \frac{1}{2}[2n - x + a + 2]
\]  

(3)

Solving Equation (3) for the quantity \( x = 2n \) and substituting the result into Equation (1) results in the Equation (4) which expresses the specific Z value as a function of the number of rings plus double/triple bonds

\[
Z(N_xO_yS_z) = a + 2(1 - R)
\]  

(4)

Figure 1 contains a representative number of examples that illustrate the application of the specific Z series concept, the use of the Z values for functional groups in Table 1 and the relation between the specific Z value and the number of rings plus double/triple bonds. In the opinion of the author, the practice of referring to the specific Z value as the hydrogen deficiency should be discontinued for several reasons. For example, consider naphthalene (C\(_{10}\)H\(_8\)) which from Equation (1) has a specific Z value of \(-12(\text{H})\). As applied to this compound, a logical question that never seems to be answered is what is the chemical significance of the statement
that naphthalene has a hydrogen deficiency of $-12$? A definition of hydrogen deficiency that has been used is the difference in the number of hydrogens between a compound and the alkane with the same number of carbons. Although this definition gives correct $Z$ values for some species it is not generally valid because it predicts a specific $Z$ value of $-14$ for naphthalene, that is, the difference in hydrogen numbers between $\text{C}_{10}\text{H}_8$ and $\text{C}_{10}\text{H}_{22}$ is $-14$. Addition of 12 hydrogens to naphthalene would presumably result in cyclodecane or a set of isomeric decenes. Another definition that can be found in the literature is the difference in hydrogen numbers between a species and a cycloalkane or an alkene. Clearly, this is a general definition with the caveat that the reference and subject species have the same carbon number. For example, consider pyrrole which has the formula $\text{C}_4\text{H}_5\text{N}$ and hence, $Z = -3$. Thus, to get the correct $Z$ value, the formula for pyrrole must be compared to an alkene or cycloalkane having four and not five carbons as the latter would yield $Z = -5$ for pyrrole. However this definition with or without the added caveat produces paradoxical results for alkanes. First, there is no alkene or cycloalkane to compare to methane. Second, the difference in hydrogen numbers between all alkanes having carbon numbers greater than 1 and the corresponding alkenes is +2. Thus, alkanes have a hydrogen deficiency of +2. That is, alkanes have an excess not a deficiency of hydrogens.

2.3 Deduction/Determination of Group Types from High-resolution Mass Spectrometric Homolog Analyses

Two concepts underlie mass spectrometric methods for homolog analysis. First, removal of an electron from a homologous series of compounds produces the corresponding series of homologous molecular ions. Thus, use of an ionization technique that generates mass spectra either dominated or characterized by the presence of molecular ions and the accurate measurement of the mass-to-charge ratios of these ions suffices to identify the homologs present in a sample. Second, the signal magnitudes of these ions allow the contribution of each of these homologs to the sample to be calculated given quantitative relationships between the isotopically most abundant molecular ion signal magnitudes and the structures of the neutral precursors to these ions. As discussed in subsequent sections, implementation of these concepts is not necessarily straightforward. However, we assume the successful implementation of them in order to consider briefly the equally important topic of determining the number of group types present in a homologous series of compounds. In general, homologs may consist of two or more isomers. The chemistry of isomers depends upon the experimental conditions. Given the compositional complexity of materials of present interest, the possibility that homologous series may contain more than one chemical (group) type should be considered by both the analysts and the chemists/chemical engineers in planning the analytical scheme and/or interpreting the results of a homolog-type analysis.

Figures 2, 3 and 4 contain carbon number distributions (CNDs) from four homolog-type analyses. The phrase “carbon number distribution” refers to the format conventionally used in reporting the results of homolog-type analyses. The numbers of the homologs identified as being present in a sample are normally calculated on
PETROLEUM AND LIQUID FOSSIL FUELS ANALYSIS

a percentage or absolute weight, mole or volume basis. The results are usually reported as a two-dimensional array. The rows or columns are the specific Z series designations for the homologous series and the columns or rows correspond to the number of carbons present in each homolog. Since the numbers of the members of each homologous series identified as being present in the sample are reported as a function of the number of carbons present in each homolog, the tabulation is termed a CND. Figures 2, 3 and 4 contain weight percentages normalized to a value of 100 for the most abundant homolog in the more abundant series, if two or more series are present.

Figure 2 contains CNDs for the \(-6(H)\) and \(-12(H)\) series obtained from high resolution field ionization (FI) mass spectra of the aromatic neutrals from chromatographic separation of coal–liquid-derived oils. (51, 59) The \(-6(H)\) aromatic series can only contain benzene, toluene and either \(n\)-alkylated benzenes or isomeric benzenes substituted with two or more alkyl groups or both. Thus, we conclude that the \(-6(H)\) CND in Figure 2 reflects the presence of a single group-type consisting of homologs of benzene which have 3–23 alkyl carbons.

The nature of a CND can often yield significant inferences concerning the presence or absence of more than one group type in a homologous series. For example, in Figure 2 the first member in the \(-12(H)\) series has the formula \(\text{C}_{10}\text{H}_8\) and, hence, reflects the presence of naphthalene. This result, the shape of the distribution and the fact that the \(\text{C}_{10}–\text{C}_{16}\) homologs dominate the distribution, leads to the conclusion that the \(-12(H)\) series is reasonably attributed to the presence of a single group type, that is, naphthalene and its alkylated homologs. However, definitely to exclude compound types such as \((1–4)\) as significant contributors to the \(-12(H)\) series would require additional experiments such as performing HRMS analyses on fractions obtained from a ring number separation of the aromatic neutrals.

The bimodal CND for the \(-18(H)\) series in Figure 3 clearly indicates the presence of at least two group types. The first homolog in the series has the formula \(\text{C}_{14}\text{H}_{10}\) and is attributed to the presence of anthracene \((5)\) and/or phenanthrene \((6)\). Either one or both of these hydrocarbons containing 1–6 alkyl carbons undoubtedly contributes to the \(\text{C}_{15}–\text{C}_{20}\) homologs. However, the shape of the distribution is evidence that at least one additional group type contributes to homologs which have carbon numbers greater than 20. As seen in Figure 3, the CNDs for the \(-18(H)\) series from the HRMS analyses of the fractions from the ring number separation of the total aromatic neutrals substantiates this conclusion. The results for the monoaromatic or first ring fraction reveal the presence of a group type consistent with the presence of hydrocarbons containing one aromatic and six naphthene rings such as \((7)\) and their alkylated homologs. The results for the second ring fraction support the presence of a diaromatic chemical type reflecting the presence of hydrocarbons such as triphenylcyclophanthalenes and alkylated homologs of these hydrocarbons. The results for the third ring fraction confirm the presence of a three aromatic ring chemical-type containing 14–36 carbons.

CNDs for the \(-14(H)\) series in an anthracene oil and one of the products from its hydrotreating are reproduced in Figure 4. (60) The distribution for the feed is consistent with the presence of a single chemical type. This conclusion is supported by gas chromatography/mass spectrometry (GC/MS) analysis which revealed thatacenaphthene \((8)\) and biphenyl \((9)\) accounted for 94% and

![Graph](image_url)

**Figure 4** CNDs for the \(-14(H)\) Z series in an anthracene oil and in a hydrotreated product. \(\bigcirc\), in feed; \(\Delta\), in products; \(\times\), feed group-type in products; \(+\), nonfeed-type(s) in products.
6% of the first homolog, respectively. The CND for the \(-14(H)\) series in the products shows that hydrotreating deceased the weight percentages of the \(C_{12}\) and \(C_{13}\) homologs and resulted in significant increases in the amounts of the \(C_{14} - C_{18}\) homologs. This and other results show the occurrence of both hydrogenation reactions introducing hydroaromatics such as (10) and (11) and hydrogenation/hydrogenolysis reactions introducing aromatics such as (12) and (13) into the \(-14(H)\) series. Estimates of the percentage contributions of (8) and (9) and homologs of these hydrocarbons and products formed from the hydrogenation of phenanthrenes (10) and (11) and hydrogenation/hydrogenolysis of phenanthrene (12) and pyrene (13) to the \(-14(H)\) series in the products are shown in Figure 4. These estimates were obtained by assuming that the \(C_{13} - C_{18}\) homologs in the feed undergo the same percentage decrease as does the \(C_{12}\) homolog.

High-resolution low-voltage electron ionization mass spectra (HRLVEIMS) of fossil fuel materials which have atmospheric equivalent boiling points (AEBP) up to about 1050°F (566°C) will in general contain series of molecular and fragment ions. The fragmentation processes undergone by molecular ions in a given homologous series and the yields of these ions relative to the molecular ions depends upon a number of factors which are considered in section 7. What is of present interest is the fact that the presence of these fragment ions must be taken into account in processing mass spectra in order to avoid erroneous conclusions regarding the group types present in a sample. The occurrence of this phenomena is illustrated in Figure 5, which contains a plot of the \(-6(H)\) homolog molecular ion relative abundances versus carbon number and could be interpreted as reflecting the presence of a \(-6(H)\) series in a \(>650°F\) (343°C) AEBP distillate that contains homologs with carbon numbers ranging from \(7-40\). However, such a conclusion would be erroneous for two reasons. First, the initial carbon number in the series would be expected to be about 15, based upon the boiling range of the sample. Second, one fragmentation reaction of benzene molecular ions substituted with relatively long-chain alkyl groups phenomenologically involves hydrogen transfer from the alkyl group to the ring with loss of an alkene resulting in formation of parent ions. Although this process is dominated by \(\alpha\)-cleavage at 70 eV, it becomes relatively important at low voltage. Thus, the ion abundances from carbon numbers 7 to about 14 are attributed to the occurrence of such rearrangement fragmentation reactions.

3 SAMPLE PREPARATION

It is generally necessary to subject crude oils, syncrudes and materials derived from their processing to physical and/or chemical separations prior to determining the compositions of these materials. An in-depth discussion of the numerous techniques available for performing these separations is clearly beyond the scope of this article. Rather the intent of this section is simply to provide the reader with an overview of a number of approaches to generating fractions that are suitable for analysis. The reader should be aware of the fact that the approach to separating a given material appears often to be determined either by the past history of the analytical chemistry of a given fossil fuel material or by the preferences of a given research group.

3.1 Distillation

Distillation is an important technique in the characterizations of crude oils. It has also been employed as the
first step in the analysis of other fossil fuel materials such as coal liquids and shale oils. Atmospheric pressure distillations resulting in distillate fractions boiling up to approximately 650°F (343°C) are conventionally performed using the American Society of Testing and Materials (ASTM) method D2892. Middle distillates contain compounds boiling from about 400 to about 650°F (205–343°C). Gas oils or vacuum gas oils which have AEBPs ranging from approximately 650°F (343°C) to approximately 1050°F (566°C) are obtained by distilling the residue from a D2892 distillation at reduced pressure using ASTM method D1160.(103) Compounds having AEBPs up to about 1300–1400°F (705–760°C) can be recovered from a D1160 vacuum residue using the technique of molecular distillation.(104,105) It should be noted that these distillations produce fractions that do not have sharp cut points in terms of composition, with the degree of overlap tending to increase with increasing boiling point. Distillate cuts boiling up to 400°F (205°C) are amenable to analysis using techniques such as gas chromatography (GC) and combined GC/MS. Applications of HRMS group-type methods are usually limited to distillate cuts having initial AEBPs of at least 400°F (205°C).

3.2 Solvent Separations – Solvent Extractions

The development of coal-liquefaction technology has historically used the technique of solvent separation or solvent extraction to separate coal-derived liquids into fractions termed oils (maltenes), asphaltenes and preasphaltenes. The technique has also been applied to other materials such as bitumens. A high-performance liquid chromatography (HPLC) solvent fractionation technique based upon the solubility properties of solvents has been described. Acidic and basic chemical extraction techniques have been used to recover basic and acidic compounds from syncrudes and petroleum. It should be noted that the fractions obtained from solvent extractions are operationally defined in terms of the procedure used to generate them.

3.3 Liquid Chromatography

Liquid chromatography is used to separate crude oils, syncrudes and materials derived from their processing into compound classes. The nature of the fractions resulting from these separations are operationally defined in terms of the procedure used to generate them. One approach is to separate a sample into classes of compounds that exhibit for a given procedure either acidic, basic or neutral chemical properties. One method for generating acidic and basic compound classes uses ion-exchange chromatography to remove compounds that exhibit acidic and basic properties with respect to anion and cation resins, respectively. Chromatography using FeCl₃ impregnated Attapulgus clay as the stationary phase has been used to remove nitrogenous compounds present in neutral fractions. A second technique for isolating acids and bases involves chromatography over acidic and basic alumina to recover compounds that exhibit basic and acidic properties, respectively. A number of chromatographic procedures have been developed for separating neutral fractions into saturated and aromatic compound classes. Solid–liquid chromatography using activated silica gel is required to separate saturates from aromatic neutrals. This separation can be performed using either HPLC or open column (low pressure) chromatography. Gradient elution chromatography through a dual-packed adsorption column containing silica gel and alumina has been used to separate neutral concentrates into saturate and operationally defined monoaromatic, diaromatic and polyaromatic-polar fractions, that is, compounds containing one, two, three or more aromatic rings and/or heteroatoms. Preparative scale HPLC procedures employing stationary phases such as chemically bonded aminopropylsilica and bonded charge-transfer agents have been developed for fractionating aromatic neutral fractions into operationally defined compound classes such as monoaromatics, diaromatics, triaromatics and tetra and greater aromatics, that is, compounds containing one, two, three and four or more aromatic rings. It should be noted that the resolution achieved in these separations decreases with increasing boiling point.

4 SAMPLE INTRODUCTION

4.1 All Glass Heated (Batch) Inlet Systems

The introduction of fossil-fuel materials having AEBPs up to about 1050°F (566°C) requires an inlet system capable of being heated and evacuated. The design should be compatible with the introduction of liquids and solids. Quantitative analysis of mass spectral data is necessarily simplified if the composition of the vapor entering the ion source is, at all times, functionally related to the original composition of the sample under analysis. Therefore, a reservoir of known volume is incorporated into the inlet system and a leak of known leak rate is inserted between the reservoir and the ion source. The sample is first expanded into the reservoir, hence, the term expansion volume, and then allowed to flow from the reservoir to the ion source via the leak. The glass line connecting the inlet system to the ion source housing is conventionally termed the leak line. The device which connects to the leak line at the source housing and conducts the vapor to the ion
source is termed the reentrance. All components of the inlet system including the leak line and the reentrance should be capable of achieving and maintaining the same temperature.

4.1.1 Inlet Designs

The first successful reservoir–inlet system meeting these criteria was developed by Lumpkin and Taylor. Gallium was used to maintain the integrity of the vacuum within the inlet system during sample introduction. A capillary pipette was used to introduce volatile liquids via a gallium-covered fritted disk. Solids and relatively nonvolatile liquids were introduced using a removable, heatable holder containing gallium. All subsequently designed high-temperature reservoir inlet systems familiar to the author can be considered to be variants of the Lumpkin–Taylor inlet.

Recent versions of this inlet are described below.

The Brunfeldt AGHIS was a joint development between R.J. Brunfeldt of the Brunfeldt Co., Bartlesville, OK (presently located in Bixby, OK) and the author and other members of the Instrumental Section at the Bartlesville Energy Technology Center, US Department of Energy, Bartlesville, OK. The basic approach was to design an inlet system incorporating new technology while maintaining the salient concepts of the Lumpkin–Taylor inlet. The methods for sample introduction and for actuating the magnetically operated valves within the oven are shown in Figure 6. Figure 7 shows the construction of the oven and the components of the inlet system within the oven.

As shown in Figure 6, the valve lifters are activated by controls on the bottom of the oven. This design allows for immediate direct access to the interior of the oven by simply lifting off the top cover of the oven. The availability of high-temperature GC septums exhibiting negligible bleed permitted use of a heatable septum inlet for introduction of relatively nonviscous liquids as shown in Figure 6. Figure 6 also shows that a removable glass cup which is heated by an independent oven permits the introduction of solids and liquids having a wide range of volatilities because the initial temperature of the cup can be subambient. Optically flat glass surfaces on the top of the cup and at the end of the glass line exiting the oven assures the integrity of the vacuum.

As seen in Figure 7, the oven incorporates a reservoir which has a volume of 900 mL. Figure 7 also shows the use of high-temperature ceramic insulation to maintain excellent temperature control within the oven. The sections of the septum inlet and the leak line passing through the oven walls are encased in aluminum blocks containing cartridge heaters in order to eliminate cold spots. As is evident in Figure 7, difficulties in performing any required maintenance is minimized by the capability of simply accessing the interior of the oven and by the location of components in the oven. The use of large diameter sample lines provides for rapid and complete residual sample removal. In order to achieve significantly reduced leak rates across the ball valves, each valve
is fabricated from glasses having dissimilar hardness. Placement of the valves provides for nonsynergistic variations of pressures within the inlet system.

The design of the reentrance needs to allow for expansion/contraction of the ion source as it is heated/cooled while maintaining good transport of the vaporized compounds into the ion source. With respect to the Kratos MS-50, this requirement was met by installing a Brunfeldt reentrance. This design incorporates threads on the end of the stainless steel housing of the reentrance which is mated via a vacuum flange and a gold gasket to a port in the ion source housing. A bellows and a threaded collar are used to vary the distance between the ion source and the reentrance tube. A thin glass helix inserted in the transfer line in the inlet oven allows for changes in the position of the leak line as the distance between the reentrance glass tube and the ion source is varied. The distance between the glass tube and the ion source is increased/decreased by decreasing/increasing the number of turns of the collar on the reentrance housing threads. For example, with the bellows in a relaxed position, the inlet oven, the leak line, the reentrance glass tube and the ion source are brought to a desired temperature. An aliquot of p-xylene is admitted to the inlet and the increase in the signal magnitude of the \( m/z \) 106 ion is monitored as the bellows is compressed to reduce the distance between the reentrance tube and the ion source. The onset of a decrease in the ion signal magnitude is used to establish the occurrence of contact between a port in the ion source and the reentrance tube. The collar is then turned in the opposite direction to relax the bellows first to remaximize the ion signal and then to decrease the ion signal slightly in order to achieve a slight distance between the ion source port and the reentrance glass tube. This procedure has been found to give good transfer of vapor into the ion source while maintaining excellent alignment of the source which is critical for achieving optimum performance of the mass spectrometer at high resolving powers (RPs). In addition, use of this reentrance was found significantly to reduce contamination of both the ion source housing and the glass electrical feedthroughs on the end flange of the ion source.

A turbomolecular pump backed by a mechanical pump is used to reduce the pressure in the system to less than \( 10^{-3} \) Torr \( [1 \text{ Torr} = (101 \text{ 325/760}) \text{ N m}^{-2}] \) as measured by a thermocouple gauge. The design of the power supplies that provide electrical power to the heaters incorporates temperature regulators connected to thermocouples. Thus, the temperatures in the various sections of the inlet including the cup inlet, oven, leak line and reentrance are controlled to within about \( \pm 2 \) °C. Temperatures as high as 325 °C are maintained routinely. The septum inlet has been operated at temperatures as high as 325 °C without noticeable thermal deterioration of the septum, although temperatures up to 300 °C are more commonly used. The time required to raise the temperature of the cup inlet to a given value can be significantly reduced by preheating the door heater shown in Figure 6, for example, the temperature in the cup-inlet oven rose from ambient to 300 °C in about 75 s after preheating the oven for about 4 min.

Gallegos and Pazzi reported the design of a miniature batch inlet system that they termed a dynamic batch inlet system (DBIS). The system incorporated an expansion bulb with a volume of only 2 mL and was used in conjunction with a gas chromatograph. The bulb was placed in the GC oven with the inlet and outlet lines connected to the GC injector and the MS ion source using deactivated uncoated 0.25-mm fused-silica capillary tubing. Hydrogen was used as the carrier gas at a flow rate of about 1 mL min\(^{-1}\). The temperatures of the injector, oven and transfer line were set to 300 °C. Injection volumes of samples such as a 350–550 °C AE\( \text{BP} \) distillate cut were 0.02–0.05 µL.

Roussis and Cameron evaluated the operational characteristics of a modified version of the Gallegos and Pazzi DBIS fabricated by the Brunfeldt Company. Substitution of helium for hydrogen as the carrier gas and variations in the dimensions of the capillary lines resulted in residence times of at least 15 min. The ability to introduce samples without using a carrier gas was also reported. Excellent agreement was obtained between the results of low-resolution type analyses performed using the DBIS for sample introduction and the corresponding results obtained using a Brunfeldt AGHIS for sample introduction.

The following are several issues that must be addressed in any consideration of substituting a DBIS for an A\( \text{GHIS} \) in HRMS-type analysis. Although the ability to use small sample sizes would be a clear advantage of a DBIS over an A\( \text{GHIS} \), which generally require samples sizes of 5–12 mg, the actual sample sizes required in HRMS applications and the implications for the required volume of the reservoir and the dimensions of the capillary lines connected to the DBIS would have to be determined. In addition, a further increase in the residence time would be required to permit acquisition of HRLVEIMS at a magnetic field scan rate of 1000 s/mass decade, for example, the time for acquiring 40 000–50 000 RP spectra at a magnetic field scan rate of 1000 s/decade is typically greater than 16 min. Also, design changes that would reduce the time-dependent variation in the ion signal magnitude observed by Roussis and Cameron and that would provide the capability for introducing viscous liquids and solids and for evacuating samples would be mandatory.

The problems encountered by the author and coworkers in attempting to use a GC oven-based inlet system developed by The Brunfeldt Company are relevant in regard to attempting to develop a DBIS for use in HRMS
group-type analyses. Vaporized samples were transferred from the reservoir to the ion source of the mass spectrometer using deactivated fused silica capillary tubing via the heated GC reentrance. Satisfactory flow rates and stable ion signal magnitudes were obtained by empirically adjusting the dimensions of the capillary tubing. The inlet system incorporated septum and cup-based inlets for introduction of liquids and solids. Unfortunately, the design placed these inlets inside of the GC oven. Thus, the introduction of samples required that the GC oven be cooled to room temperature. The excessive time required to raise the temperature to say 300 °C using only the GC oven heater was addressed by installing but not without problems an additional heater in the GC oven. A more serious problem that was never satisfactorily resolved was the effect of GC blower fan vibrations on 40 000 RP low-voltage electron ionization (LVEI) mass spectra.

4.1.2 Effusive Flow and the Time Dependence of Ion Yields

We now consider the effect of the time dependence of the sample composition in the reservoir on the relative ion abundances (RIAs). Since the rate of effusion of a gaseous species follows molecular flow and is inversely proportional to the square root of its mass, the partial pressures of the components in the reservoir are time dependent. Thus, the composition of the gas flowing into the ion source is time dependent. The effect of neglecting to correct for this phenomenon on the accuracy of an analysis reflects the rate of effusion through the leak in relation to the masses of the gaseous species, the vacuum-seal integrity of the inlet system, mass spectral acquisition time and the reproducibility in the mass spectra. In order to assess the magnitude of the problem, let \( N_i \) be the number of moles of the \( i \)th species having molecular weight \( MW_i \) in the inlet at time \( t \) and at temperature \( T(K) \). Neglecting the steady state pressure in the ion source, the rate of decrease in \( N_i \) is

\[
\frac{dN_i}{dt} = \frac{AN_i}{V} \frac{RT}{2\pi MW_i} \left( \frac{1}{z} \right) \tag{5}
\]

where \( A \) is the cross-sectional area (cm\(^2\)) of the leak, \( R \) is the gas constant \((8.314 \times 10^7 \text{ erg K}^{-1} \text{ mol}^{-1})\) and \( V \) is the volume of the reservoir plus the glass line between the reservoir and the leak. Integrating Equation (5) between the limits \( N(t_f), t_f \) and \( N(t_i), t_i \), we obtain Equation (6)

\[
\ln \frac{N(t_i)}{N(t_f)} = -k_{eff}(t_f - t_i) \tag{6}
\]

where

\[
k_{eff} = \frac{A}{V} \frac{RT}{2\pi MW_i} \left( \frac{1}{z} \right) \tag{7}
\]

The rate of effusion of air through a leak was found to be 0.21 cm s\(^{-1}\) at 298 K. Thus, Equation (7) yields an area of \( 1.80 \times 10^{-5} \text{ cm}^2 \) for the leak. The area of the leak was independently determined by monitoring the time dependence of the intensity of the molecular ion of acetone. The \( m/z \) 58 intensity decreased by a factor of two in 2398 s. Since the inlet temperature was 573 K and since \( V \) is 930 cm\(^3\), Equations (6) and (7) yield an area of \( 2.35 \times 10^{-5} \text{ cm}^2 \). The good agreement between the two independent methods for determining the cross-sectional area of the leak demonstrates the vacuum-seal integrity of the inlet system.

The time dependence of the composition of a gaseous mixture in a reservoir inlet is considered assuming a mixture initially composed of equal moles of \(-6(H)\) series homologs. Assume that the magnetic field was scanned exponentially from \( m/z \) 650 to \( m/z \) 70 at 100 s/decade. Acquisition of mass spectra rather than elapsed time is of immediate relevance to the analyst. Therefore, Table 2 presents the effect of effusion of components across the leak on the composition of the mixture in the inlet as a function of the mass spectrum number rather than as a function of elapsed time following introduction of the sample into the ion source. In Table 2, the effusion constants in column 3 were calculated for the masses in column 2 using the values in footnote a. The values in column 4 are the arrival times for the seven molecular ions in a given mass spectrum calculated using the value specified in footnote c. Columns 5 reveal that the moles of each of the seven components remaining in the inlet relative to the initial moles at the time of detection of each molecular ion in each of the ten mass spectra. As noted in footnote d, these values were calculated using the effusion constants and times in columns 3 and 4, respectively, assuming an elapsed time of 5 min between sample introduction to the ion source and initiation of the first scan and a total time of 6 s between scans.

Comparison of the mole ratios in columns 6 through 15 of Table 2 with the corresponding initial ratios in column 5 reveals that the moles of each component and, hence, their partial pressures, decrease with increasing time. The decrease in these quantities is seen to increase, as expected, with decreasing molecular weight. Therefore, the number of molecules of each component entering the ion source per unit of time diminishes as time increases with the diminution becoming larger as the molecular weight decreases. Consequently, consecutive scans of the mass spectrum of the mixture will exhibit progressively smaller values for both the molecular-ion signal magnitudes and the total ionization. In order to assess the impact of these observations on the accuracy of a quantitative analysis, it is useful to express the time dependence of the composition of the vapor remaining

\( ^{a} \) Values in columns 3 through 12 calculated from values in columns 6 through 15 in Table 2, respectively.

in the inlet in terms of the mole ratios normalized to the moles of one component because these values are directly proportional to the relative molecular-ion signal magnitudes observed in the mass spectra of a mixture. The values calculated from the relative mole ratios in Table 2 are tabulated in columns 3 through 12 of Table 3. Assuming all other factors to be equal, the relative mole ratios in Table 3 reveal that incorrect molecular ion abundance ratios will be observed in all ten mass spectra. The error in the RIAs increases with decreasing mass for a given spectrum and becomes larger as the spectrum number rises for a given mass. Thus, neglecting to account for changes in the composition of the vapor within the reservoir inlet during acquisition of the mass spectra will introduce errors into a quantitative analysis provided that other experimental errors are less than the changes in composition on a percentage basis. Under this assumption, the variations in the mole ratios shown in Table 3 would, unless accounted for, negate the increase in accuracy obtained by averaging the corresponding molecular ion signal magnitudes in the ten scans of the mass spectrum of the mixture.

We now consider the effect of decreasing the cross-sectional area of the leak on the composition of the vapor in the reservoir during acquisition of a mass spectrum at 1000 s/decade rather than at 100 s/decade. For this scan rate, columns 5 and 6 of Table 4 give the moles of each of the seven components relative to the moles of C\(_{42}\)H\(_{78}\) remaining in the inlet at the times for detection of the corresponding molecular ions calculated for cross-sectional areas of the leak of 2 \( \times 10^{-2} \) and 3 \( \times 10^{-2} \) cm\(^2\), respectively. For the purposes of comparison, the values of the remaining parameters in these calculations were identical to those used in calculating the mole ratios in Tables 2 and 3. Comparison of the mole ratios in columns 5 and 6 of Table 4 reveals that a reduction of ca. 64% in the cross-sectional area of the leak significantly reduces the alteration in the composition of the vapor in the inlet during acquisition of the mass spectrum of the mixture. Such a reduction in
the cross-sectional area of the leak significantly reduces the contribution of the mass dependence of effusion across the leak to the error in analysis especially for the lower mass compounds. Since the times for acquiring one spectrum of the mixture at a magnetic field scan rate of 1000 s/decade and ten spectra of the mixture at a magnetic field scan rate of 100 s/decade are very similar, use of the leak with the smaller cross-sectional area would significantly reduce the variation in the relative mole ratios shown in Tables 2 and 3.

4.1.3 Processing of Mass Spectra

The time dependence of the ion signal magnitudes should obey Equation (6). Thus, the errors introduced into an analysis by changes in the composition of the vapor in the inlet during the time required for acquisition of a mass spectrum can be minimized by extrapolating the logarithm of the ion signal magnitudes to zero time. With respect to mass spectra acquired at 100 s/decade for our hypothetical mixture, the quantitative analysis would employ the seven average molecular ion signal magnitudes calculated from the ten zero-time signal magnitudes for each ion which were obtained by a least-squares fit of the individual signal magnitudes in each of the ten spectra to Equation (6). The times listed in column 3 of Table 4 reveal the impracticality of acquiring multiple scans of a mass spectrum at a magnetic field scan rate of 1000 s/decade if the components in a mixture cover a reasonable mass range. A possible approach to minimizing the error in such situations would be to calculate effusion constants for the various components in the mixture using Equation (7). These values and both the arrival times and signal magnitudes of the corresponding ions would be substituted into Equation (6) to arrive at estimated zero-time signal magnitudes for these ions.

An experimental approach to accounting for the mass dependence of effusive flow would be to acquire mass spectra under conditions of constant timing. The mass spectra of samples would be acquired under conditions such that the signal magnitudes of the various ions are recorded at the same time intervals following introduction of each sample into the reservoir inlet. The sensitivities for those ion \( m/z \) values to be used in the analyses are either determined at the same time intervals or calculated at these time intervals from values measured at other known time intervals. Consequently, the signal magnitudes of these ions in the spectra of both the mixtures of unknown composition and the calibrating substance or mixture would then be, within the limits of experimental accuracy, the same fractions of their zero-time signal magnitudes. Since the ion signal magnitudes obtained under these conditions are directly used in calculating quantitative distributions, time has been experimentally eliminated as an independent variable. This approach is especially useful in the analysis of mixtures of noncondensable gases.

The aforementioned approaches to accounting for the compositional dependence of ion signal magnitudes are extremely tedious and time-consuming. Thus, a decision regarding implementation of such data analyses should include a consideration of the uncertainties in the ion signal magnitudes and the availability of ionization sensitivities. The accuracy of the ion abundances reflects both the ion statistics and the variation in instrumental parameters governing the generation, extraction, transmission and detection of the ions. The factors which determine the ion statistics for the various \( m/z \) values include the amounts of each component charged, the cross-sectional area of the leak significantly reduces the contribution of the mass dependence of effusion across the leak to the error in analysis especially for the lower mass compounds. Since the times for acquiring one spectrum of the mixture at a magnetic field scan rate of 1000 s/decade and ten spectra of the mixture at a magnetic field scan rate of 100 s/decade are very similar, use of the leak with the smaller cross-sectional area would significantly reduce the variation in the relative mole ratios shown in Tables 2 and 3.

4.1.3 Processing of Mass Spectra

The time dependence of the ion signal magnitudes should obey Equation (6). Thus, the errors introduced into an analysis by changes in the composition of the vapor in the inlet during the time required for acquisition of a mass spectrum can be minimized by extrapolating the logarithm of the ion signal magnitudes to zero time. With respect to mass spectra acquired at 100 s/decade for our hypothetical mixture, the quantitative analysis would employ the seven average molecular ion signal magnitudes calculated from the ten zero-time signal magnitudes for each ion which were obtained by a least-squares fit of the individual signal magnitudes in each of the ten spectra to Equation (6). The times listed in column 3 of Table 4 reveal the impracticality of acquiring multiple scans of a mass spectrum at a magnetic field scan rate of 1000 s/decade if the components in a mixture cover a reasonable mass range. A possible approach to minimizing the error in such situations would be to calculate effusion constants for the various components in the mixture using Equation (7). These values and both the arrival times and signal magnitudes of the corresponding ions would be substituted into Equation (6) to arrive at estimated zero-time signal magnitudes for these ions.

An experimental approach to accounting for the mass dependence of effusive flow would be to acquire mass spectra under conditions of constant timing. The mass spectra of samples would be acquired under conditions such that the signal magnitudes of the various ions are recorded at the same time intervals following introduction of each sample into the reservoir inlet. The sensitivities for those ion \( m/z \) values to be used in the analyses are either determined at the same time intervals or calculated at these time intervals from values measured at other known time intervals. Consequently, the signal magnitudes of these ions in the spectra of both the mixtures of unknown composition and the calibrating substance or mixture would then be, within the limits of experimental accuracy, the same fractions of their zero-time signal magnitudes. Since the ion signal magnitudes obtained under these conditions are directly used in calculating quantitative distributions, time has been experimentally eliminated as an independent variable. This approach is especially useful in the analysis of mixtures of noncondensable gases.

The aforementioned approaches to accounting for the compositional dependence of ion signal magnitudes are extremely tedious and time-consuming. Thus, a decision regarding implementation of such data analyses should include a consideration of the uncertainties in the ion signal magnitudes and the availability of ionization sensitivities. The accuracy of the ion abundances reflects both the ion statistics and the variation in instrumental parameters governing the generation, extraction, transmission and detection of the ions. The factors which determine the ion statistics for the various \( m/z \) values include the amounts of each component charged, the

cross-sections for their ionization, and the efficiencies of extraction of ions from the source and of the transmission of ions at a given RP. In this regard, the analysis of multiple scans of the mass spectra obtained from repeated injections of various samples of present interest suggests that a standard deviation of up to about 10% in the molecular-ion relative abundances for components accounting for reasonable weight percentages of the mixtures is not atypical. As discussed later, the situation with regard to the availability of ionization sensitivities and the standard deviations associated with these values is in general unsatisfactory. Based upon these considerations, the mathematical analysis of ion signal magnitudes to account for changes in vapor composition resulting from effusion across a leak is justified in order to obtain highly accurate analysis of mixtures of noncondensible gases. However, such analyses would not in general be warranted for mixtures of condensates given reservoir–inlet system parameters similar to those considered in the present discussion. The mole ratios in Tables 2–4 support this conclusion especially for compounds having masses in excess of ca. 150 amu. Depending upon the accuracy in the ion signal magnitudes, corrections may be justified for lower molecular weight compounds. Finally, the rates of effusion are directly proportional to the cross-sectional area of the leak divided by the volume of the inlet and exhibit a half-power dependence on the absolute temperature divided by the mass of each species. For exponential scanning of the magnetic field, the change in the composition of the vapor in the inlet and, hence, the variation in the relative ion signal magnitudes are exponentially dependent upon the effusion constants and the ion-arrival times. Thus, the effect of compositional changes on accuracy can be minimized by considering the nature of the samples to be analyzed and both the rates for acquiring mass spectra and the functional form of the scan law in developing specifications for a reservoir–inlet system.

4.2 Direct Introduction Probe

The technique of direct-probe introduction of samples into a mass spectrometer ion source has been used in the MS analysis of a variety of fossil fuel materials. However, the majority of these studies involved the acquisition of either high-resolution mass spectra for the purpose of determining molecular formulas or low-resolution (unit mass resolved) mass spectra. In only several of these studies were the HRMS acquired both to identify and quantify the homologs present in samples.

4.2.1 Status of Results Obtained Using the Technique

The objectives in using a direct probe rather than an AGHIS for sample introduction are twofold: first, to increase the analyzable molecular weight range because ion-source pressures are most likely to be less than the pressures in reservoir–inlet systems and, second, to reduce any occurrences of thermal decompositions by decreasing the residence time of the gaseous molecules in the system prior to their ionization. In the opinion of the author, the studies reported to date preclude a definite assessment of the extent to which the first objective is attained for various compound classes.

Ions having m/z values ranging from about 100 up to about 1900 were observed in low-resolution FI mass spectra of probe introduced samples obtained from application of molecular distillation and sequential elution fractionation to atmospheric residues. Low resolution FI mass spectra containing ions with m/z values ranging up to about 900–1200 were obtained from probe distillation of saturated hydrocarbon and aromatic neutral fractions from a petroleum distillate having 50% point AEBPs from about 1050 to 1250 °F (566 to 677 °C). It is unfortunate that the mass spectra in these latter experiments were not also acquired at RP values exceeding linearity at RP values greater than 10 000. In this regard, it should be noted that the author has routinely observed ions having low signal magnitudes above m/z 700 in the 40 000 RP LVEI mass spectra of gas–oil–aromatic–neutral fractions introduced into the ion source via a batch inlet at 300–325 °C.

Probe distillation LVEI mass spectra of an aromatic neutral fraction from the 1000–1250 °F (538–677 °C) AEBP distillate of a different crude that were acquired at RP values ranging from 3000–10 000 exhibited ranges of ion m/z values comparable to those that are observed using batch inlet introduction. The same conclusion is indicated to account for probe distillation of the saturates and aromatic neutrals from the maltene fraction of a tar sand bitumen based upon the FI mass spectra and presumably the 70-eV electron ionization (EI) mass spectra obtained at 1000 and 10 000 RP, respectively.

The results from analysis of the 25 000 RP LVEI mass spectra of molten caustic-treated coal extracts indicate that direct probe introduction may increase to some extent the accessible molecular weight range for highly polar compounds containing one or more of the elements N, O and S. However, probe introduction resulted in only about 45% of the pyridine dialysate from one coal being vaporized. Finally, the carbon number ranges of the various hydrocarbon homologous series are consistent with those routinely introduced via a batch inlet.

The technique of probe microdistillation (PMD) was used in analyzing a vanadyl porphyrin fraction isolated from the >700 °C AEBP resid from Venezuelan crude. 
Cerro Negro. The HRLVEIMS of the volatiles were acquired at 10 000 RP. The mass spectra exhibited ions having \( m/z \) values ranging from about 500 to about 850 with the maximum ion signal magnitudes in approximately half of the −28 through −50 Z(N₄ VO) series occurring at \( m/z \) values less than 700. Approximately two-thirds of the vanadium-containing compounds were found to be distillable.

In the opinion of the author, using the technique of probe introduction to extend the range of analyzable molecular weights of various compound classes significantly requires a detailed study using both a batch inlet and a direct probe to introduce fractions from separation of various fossil fuel materials with the mass spectra acquired over a range of RPs. As discussed below, the issues that attend the incorporation of the technique of probe distillation into HRMS homolog methods would appear to justify such a study.

4.2.2 Fundamental Considerations in High-resolution Mass Spectrometric Applications

Since probe distillation of the components of a mixture occurs over a range of temperatures, the pressure of a neutral species in the region of ionization and, hence, the \( m/z \) values and signal magnitudes of the corresponding molecular ions observed in mass spectra acquired during a distillation of a sample are temperature dependent. Consequently, quantitative MS employing probe introduction requires the total signal magnitude of the molecular ions detected from the volatilization/ionization of the components as the temperature \( T_i \) of the sample in degrees Kelvin is raised from its initial value, \( T_{\text{int}} \), to its final value, \( T_{\text{fin}} \). The total signal magnitude of the \( k \)th molecular ion resulting from volatilization/ionization of the \( k \)th component in a mixture is

\[
SM(\text{Tot})_k = \frac{T_{\text{fin}}}{T_{\text{int}}} \int f(SM(T)_{k,i}) \,dT
\]  

(8)

One approach to evaluating the integral in Equation (8) is to acquire multiple mass spectra as the probe temperature is raised from its initial to its final value. The signal magnitudes of the corresponding ions in each of the acquired mass spectra are then summed to obtain a total spectrum for distillation of the sample. However, as discussed subsequently, this method for acquiring total molecular ion signal magnitudes is not applicable to the acquisition of HRMS.

When using the technique of probe distillation in performing HRMS-type analyses, Schmidt and Sprecher acquired 25 000 RP LVEI mass spectra of the components of coal extracts that were volatile at four different probe temperatures. Each spectrum at a given temperature was treated as a single analysis and solutions to Equation (8) were obtained by summing the signal magnitudes for the corresponding molecular ions in the spectra acquired at a given probe temperature to obtain a composite spectrum for that temperature. The composite mass spectrum was used to calculate CNDs and other parameters. The fact that this approach entails the acquisition of mass spectra of compounds volatilized at only selected temperatures rather than over the entire temperature range raises a question regarding the extent to which the analytical results represent the actual composition of a sample.

Schronk et al. used the method of PMD developed by Grigsby et al. in the HRMS-type analysis of a monoromatics fraction from a 1000–1250 °F (538–677 °C) AEBP petroleum distillate. Linear temperature programming at a rate of 7 °C min⁻¹ resulted in a distillation time of approximately 28 min. Since 3000 and 10 000 RP mass spectra were acquired using a magnetic field scan rate of 100 s/decade, 25 mass spectra were acquired during a distillation. Variations in the efficiency of extracting ions from an ion source generally occurs during distillations under the condition of linear temperature programming. Since these variations would introduce significant errors into the quantitative results, the ion signal magnitudes are corrected for the occurrence of these variations by acquiring mass spectra containing the signal magnitudes of both the ions from distillation/ionization of a sample and ions 1, 2, 3, . . . , \( j \) from ionization of a substance introduced via an expansion volume. The correction factor for the signal magnitudes in the \( i \)th mass spectrum acquired at \( T_i \) is, Equation (9)

\[
CF_i = \frac{\sum_{j} \sum_{i} SM_i / N}{\sum_{i} SM_i}
\]

(9)

The signal magnitude of the \( k \)th ion in the \( i \)th mass spectrum corrected for the variation in the ion source extraction efficiency is, Equation (10)

\[
SM(\text{cor})_{i,k} = SM(\text{exp})_{i,k} CF_i
\]

(10)

Equation (11) describes the functional form of \( f(SM(T)_i) \) deduced from an empirical analysis of

\[
f(SM(T)_i) = \frac{A_1 \exp(A_2/T_i)}{1 + \exp[A_3(T_i - A_4)]}
\]

(11)

the temperature dependence of the ion signal magnitudes resulting from probe distillation of pure compounds. Values of the parameters \( A_1 \) through \( A_4 \) are obtained from Equation (12) by nonlinear regression analysis

\[
SM(\text{cor})_{i,k} = \frac{A_1 \exp(A_2/T_i)}{1 + \exp[A_3(T_i - A_4)]}
\]

(12)
elaborate on the analysis of petroleum and liquid fossil fuels

Average error ± σ

RMS error ± 4.2 ± 9.8 ± 17.6
mean square (RMS) deviations for the two batch inlet experiments led us to conclude that the mixture was suitable for use in our development of a computer-based method for acquiring and processing probe temperatures and low-resolution mass spectral files. However, the results from the second batch inlet analysis are consistent with the loss of small amounts of the more volatile components indan, 1,3,5-trimethylbenzene and 1,2,3,4-tetrahydronaphthalene during storage and/or handling of the mixture. Also, the variability of the results from this analysis is generally greater than that from the first batch inlet analysis.

Columns 8 and 9 of Table 5 list the weight percentage of each component calculated from the areas under the elimination curves and the percentage deviation in each of these values, respectively. Both the average and RMS errors and the standard deviation in the average error are seen in Table 5 to be larger for the PMD FIMS analysis than for the second batch inlet FIMS analysis. Examination of column 9 reveals that the errors in the PMD FIMS analysis were less then 10% for eight compounds, 10–20% for five compounds and between 20 and 34% for six compounds. The corresponding results from the second batch inlet analysis are 13 compounds, five compounds and one compound, respectively. Thus, at least in this instance, the imprecision in the quantitative results was greater using a direct probe than a batch inlet for sample introduction. The diminished accuracy of the results may be attributed in part to the loss of volatile components upon introduction of the probe into the system and the effect of the rate of temperature increase on the volatilization of these compounds in relation to the time for spectral acquisitions. The values of 33.1%, 22.6% and 44.4% obtained from PMD FIMS analysis of a mixture consisting of 33.2% phenanthrene, 25.1% fluoranthene and 41.7% hexahydropyrene afford a measure of support for this conclusion. These results indicate the need for additional studies using both synthetic blends and fossil-fuel samples with the analytical results for both kinds of samples obtained for both probe and batch inlet introductions in order to establish the ranges in both the accuracy and the precision that are obtainable using direct probe introduction.

Significant problems must be addressed and resolved in order to implement probe introduction HRMS homolog analysis in the molecular weight range where the method(s) would have the most significance, that is, above about mass 400 u for highly polar compounds such as acids and bases and above about 700 u for aromatic neutrals and saturates. In order to begin to define these problems, we consider the probe introduction of the −20(H), −18(H), −16(H) and −32(H) homologs C_{114}H_{210}, C_{114}H_{212}, C_{114}H_{212} and C_{115}H_{198} under conditions that simulate the presence of these homologs in an aromatic neutral concentrate containing homologs of chemical types ranging in mass from about 750 u to about 1800 u. That is, the amounts of the −20(H), −18(H) and −16(H) homologs to be distilled are equivalent to 0.5 wt% of a 1-kg sample of the aromatic neutral fraction or 3.167 × 10^{-9}, 3.163 × 10^{-9} and 3.159 × 10^{-9} moles; the corresponding values for the −32(H) homolog are 0.05% and 3.163 × 10^{-10} moles. The LVEI would initially be acquired at 20000 RP in order to resolve C_{114}H_{210}, and C_{115}H_{198}, molecular ions having 10 to 1 RIA ratios; see section 6.2. We also assume that: (1) the LVEI mass spectra are characterized by the presence of molecular ions and the absence of fragment ions, (2) the mass spectra are acquired from m/z 1950 to m/z 750 using either a Kratos MS-50 mass spectrometer or an instrument that has a similar dependence of sensitivity on RP with either instrument being fitted with a high-field magnet to permit acquisition of HRLVEIMS at full accelerating voltage, and (3) the magnetic field strength is decayed exponentially at a rate of 300 s/decade with an interscan time of 4 s. The 2000 RP sensitivity for LVEI of phenanthrene is 4.4 × 10^{17} ions mol^{-1}. The ratio of the sensitivity at 20 000 RP to the sensitivity at 2000 RP is about 0.071. Making the usual assumption that LVEI sensitivities are carbon-number independent results in a 20 000 RP sensitivity for LVEI of C_{114}H_{210} of 3.12 × 10^{16} ions mol^{-1} and mole sensitivities for −20(H), −32(H) and −16(H) homologs relative to the mole sensitivity for −18(H) homologs of 1.24, 1.84 and 0.67, respectively; see section 7.7. The distributions of C_{114}H_{208}, C_{114}H_{210}, C_{114}H_{212}, and C_{115}H_{198} molecules and, hence, molecular ions containing carbon-13 but not deuterium 3C_{114}H_{210}, 3C_{114}H_{212} and 3C_{115}H_{198} molecules and, hence, 3C_{114}H_{208}, 3C_{114}H_{210}, 3C_{114}H_{212}, and 3C_{115}H_{198} molecules and, hence, molecular ions containing carbon-13 but not deuterium are 0.05% and 3.167 × 10^{-9}, 3.163 × 10^{-9} and 3.159 × 10^{-9} moles; the corresponding values for the −32(H) homolog are 0.05% and 3.163 × 10^{-10} moles. The LVEI would initially be acquired at 20000 RP in order to resolve C_{114}H_{210}, and C_{115}H_{198}, molecular ions having 10 to 1 RIA ratios; see section 6.2. We also assume that: (1) the LVEI mass spectra are characterized by the presence of molecular ions and the absence of fragment ions, (2) the mass spectra are acquired from m/z 1950 to m/z 750 using either a Kratos MS-50 mass spectrometer or an instrument that has a similar dependence of sensitivity on RP with either instrument being fitted with a high-field magnet to permit acquisition of HRLVEIMS at full accelerating voltage, and (3) the magnetic field strength is decayed exponentially at a rate of 300 s/decade with an interscan time of 4 s. The 2000 RP sensitivity for LVEI of phenanthrene is 4.4 × 10^{17} ions mol^{-1}. The ratio of the sensitivity at 20 000 RP to the sensitivity at 2000 RP is about 0.071. Making the usual assumption that LVEI sensitivities are carbon-number independent results in a 20 000 RP sensitivity for LVEI of C_{114}H_{210} of 3.12 × 10^{16} ions mol^{-1} and mole sensitivities for −20(H), −32(H) and −16(H) homologs relative to the mole sensitivity for −18(H) homologs of 1.24, 1.84 and 0.67, respectively; see section 7.7. The distributions of C_{114}H_{208}, C_{114}H_{210}, C_{114}H_{212}, and C_{115}H_{198} molecules and, hence, molecular ions containing carbon-13 but not deuterium were calculated as described in section 7.1. Molecules containing carbon-13 but not deuterium were calculated as described in section 7.1. Molecules containing carbon-13 but not deuterium were calculated as described in section 7.1. Molecules containing carbon-13 but not deuterium were calculated as described in section 7.1. Molecules containing carbon-13 but not deuterium were calculated as described in section 7.1.
Equation (14) can be used to obtain a value of \( k \) given the time it takes to scan a decade of \( m/z \) values, that is, for \( t = 300 \text{s/decade}, k = 7.6753 \times 10^{-3} \text{ s}^{-1} \). Although the actual scan law is not ideal, the author has routinely realized good agreement between theoretically predicted and experimental peak widths at 5% of the peak heights provided that the Kratos MS-50 is set up so that the RP is essentially constant over the range of \( m/z \) values being scanned.

Following Schmidt and Sprecher,\(^{(79)}\) we assume that probe introduction at temperature \( T \) resulted in a constant beam current for 10 min. Since the time for acquiring a spectrum is calculated to be 124.5 s and the interscan time is 4 s, four 20 000-RP LVEI/MS will be acquired during this time interval. For LVEI of each of the \( j = 1, 2, \ldots, 7 \) isotopically substituted \(-20(\text{H})\), \(-32(\text{H})\), \(-18(\text{H})\), and \(-16(\text{H})\) molecules, Equations (16) and (17) were solved to obtain values for the predicted total number of ions and the experimental total number of ions that include estimates of the effects of ion statistics, respectively.

\[
N_{ij} = NOS \times \text{floor} \left( \frac{1}{2} \frac{\text{moles} \left[ -Z(\text{H}) \right] \times \text{PA}_{ij}}{DT} \times S(\text{mol})_{i=3} \times RS(\text{mol}) \times Pw_{RP} \right) \quad (16)
\]

\[
N_{exp_{ij}} = N_{ij} + \text{floor}(r_{ij} \sqrt{N_{ij}}) \quad (17)
\]

In Equation (16), \( NOS \) is the number of acquired mass spectra, \( \text{PA}_{ij} \) are the percentage abundances of the seven isotopically substituted molecules/molecular ions, \( S(\text{mol})_{i=3} \) is the mole sensitivity for LVEI of \( C_{114}H_{210} \) at 20 000 RP, \( RS(\text{mol}) \) are the relative mole sensitivities for LVEI of \( C_{114}H_{208}, C_{115}H_{198}, C_{114}H_{210} \) and \( C_{114}H_{212} \) at temperature \( T \). The specific \( Z \) values and the formulas of the various isotopically substituted molecular ions are listed in columns 2 and 3, respectively. Columns 4 and 5 contain normalized percentage abundances of \(-20(\text{H}), -18(\text{H}) \) and \(-16(\text{H})\) molecular ions and \(-32(\text{H})\) molecular ions, respectively, calculated from the percentage abundances in Table 6. The \( m/z \) values and the predicted ion abundances in Table 6 are shown in columns 6 and 7, respectively. The \( m/z \) values and the abundances of the ions in the composite “experimental” spectrum are tabulated in columns 8 and 9, respectively. The following procedure was used to obtain experimental \( m/z \) values and abundances for unresolved peaks. Equations (18) and (19) were solved to obtain a \( m/z \) value and an experimental ion abundance. Solutions to Equation (19) and the known \( m/z \) values for resolved peaks were

\[
\text{ions} = \sum_{i} N_{ij} \quad (18)
\]

\[
\text{m/z} = \frac{\sum_{i} N_{ij} \times m/z_{i,j}}{\text{ions}} \quad (19)
\]

subject to a 5-ppm error multiplied by random numbers having normal distributions with \( \mu = 0 \) and \( \sigma = 1 \). The entries in columns 10–13 are the results obtained from deisotoping/formula assignment of the \( m/z \) signal magnitude pairs using Equations (18) and (19) as described in Gaun et al.\(^{(92)}\)

The mass measurement errors in column 12 are seen to be typical of the values encountered in processing HRLVEIMS in the “conventional” mass range. The
Table 6: Quantities relevant to predicting mass spectra for direct probe introduction of \((\text{CH}_2)_n\) at temperature \(T\)

<sup>a</sup> Mass-to-charge measurement error in parts per million, i.e. values in column 6 minus values in column 11 divided by values in column 11 multiplied by 10<sup>6</sup>.<br>
<sup>b</sup> Percentage differences between predicted numbers of ions in column 7 and the numbers of ions after deisotoping spectra in column 10.

Percentage deviations in the ion abundances in column 13 in relation to the ion abundances in column 9 are similar to the repeatability that can be attained in ion abundances calculated from the signal magnitudes in HRLVEIMS in the “conventional” mass range. Subject to a number of considerations, Tables 6 and 7 indicate the desirability of performing well-conceived experiments to assess the feasibility of using probe distillation to extend homolog-type analysis to aromatic hydrocarbon fractions having AEBPs up to about 1400 °F (760 °C). The assumed absence of fragment ions is most likely to be invalid for LVEI. The presence of significant numbers of fragment ions relative to molecular ions would undoubtedly complicate spectral interpretations. For example, hydrogen atom loss from C114H210 would result in the formation of C114H209+ with a mass that differs from the mass of the –20(H) ion 13CC113H208 by only 4.5 mmu (milli-mass units). Since deisotoping of the experimental ion abundances will be necessary especially with DF instruments, decisions regarding the composition/origin of the ion masses in a sequence will be required. For example, for Table 7 a decision would have to be made regarding the value of a residual abundance for ion 2 that would be attributed to the presence of C114H209 fragment ions rather than to ion statistics and/or variations in the abundance of carbon-13/deuterium. In addition, the loss of two hydrogens or H2 from C114H210 would result in the formation of C114H208. Thus, a decision would be required
about the extent to which the signal magnitude of the mass 1577.6276 ion reflects the presence of a –20(H) homolog in the sample. This extension of homolog methods would clearly benefit from the implementation/development of ionization techniques resulting in mass spectra characterized by the presence of molecular ions, the essential absence of fragment ions and by the development of separation techniques producing well-defined ring number fractions. Also, FTICR MS could be an important technique in method development given the RPs that have been achieved to date in the LVEI mass spectra of lower boiling petroleum distillates. Finally, the procedure to be used in calculating CNDs must be addressed. The usual practice in the “conventional” mass range is to base the calculation of these distributions on the signal magnitudes of the isotopically most-abundant molecular ions. However, as seen in Tables 6 and 7 the dominance of a distribution of molecular ion signal magnitudes by a single isotopic molecular ion decreases with increasing mass-to-charge ratio.

5 IONIZATION TECHNIQUES: APPLICATIONS

5.1 Low-voltage Electron Ionization

For various reasons LVEI is the principal ionization technique used in the HRMS method for determining group types. (See refs. 6, 8, 10, 11, 13, 15–17, 19–24, 26, 31–35, 37–39, 41, 44, 47, 48, 52, 53, 61, 62, 71, 72, 75, 79, 82, 85, 86, 88, 91–94, 97) A number of commercial ion sources can be operated at low voltage without significant if any modification in a well maintained and optimally tuned DF mass spectrometer such as the Kratos MS-50 to generate ion beams that are intense enough for the routine acquisition of mass spectra of distillates at RPs ranging up to about 50 000. A number of analysts including the author have acquired HRLVEIMS at RPs ranging up to 80 000–100 000. The technique is applicable to neutral, acidic and basic aromatic compound types. However, aromatic carboxylic acids are undoubtly an exception. For example, the author has normally observed significant numbers of molecular ions phenomenologically corresponding to the ionization of homologs of various aromatic hydrocarbon types in the HRLVEIMS of acid fractions which are known from 13C NMR (nuclear magnetic resonance) and IR (infrared) spectroscopy to contain carboxylic acids. The LVEI technique is not applicable to saturate fractions.

5.2 Field Ionization

The technique of FI has been shown to be applicable to the mass spectrometric analysis of distillates boiling up to 400°F (204°C) and saturate, aromatic neutral, acidic and basic fractions from higher boiling distillates. However, FIMS has not enjoyed wide acceptance for a number of reasons. FI sources are not commercially available for all mass spectrometers. Achieving optimum performance of the source on a routine basis is often tedious and difficult. The majority of FI applications have involved the acquisition of low-resolution spectra.

With this in mind, it should be noted that unit resolution FI mass spectra suffice for the determination of CNDs for saturate fractions. The technique has found few applications in HRMS homolog analysis. Acquisition of mass spectra with adequate ion abundances using a DF mass spectrometer equipped with an FI source is limited under the best of conditions to RPs of less then about 10 000. One approach to using FIMS to determine CNDs involved a convoluted process. FIMS were data system acquired at about 2000 RP and oscillographically recorded at 7500–10 000-RP. The heights of resolved and partially resolved peaks in the latter spectra were hand measured and the nominal m/z values of these ions were interpreted in terms of the formulas assigned to ion m/z values observed in the 20 000 or greater RP 70-eV spectra recorded on photoplates. These results were then used to factor the ion abundances in the 2000 RP FIMS into signal magnitudes for the various homologous molecular ions. Using a Kratos MS-50 equipped with a combination FI/EI ion source, Parisi and Scheckle determined CND for low-boiling distillates from FIMS data system acquired at about 7500 RP. The known masses of +2(H) ions were used to convert the time centroids of the peaks in the spectra to masses.

5.3 Other Ionization Techniques

The techniques of chemical ionization (CI), charge exchange (CE) and fast atom bombardment (FAB) have received consideration as alternative ionization techniques in type analysis. The results as described below indicate the possibility of using one or more of these techniques to circumvent a number of existing problems in HRMS homolog-type analysis.

Veloski et al. reported the acquisition of mass spectra of a coal derived distillate and a petroleum-derived residuum obtained at a static RP of 20 000 with ion formation accomplished using low-pressure ammonia CI and LVEI. The ammonia CI results are especially significant because of the problem, as discussed by both the authors and subsequently in sections 6.3 and 6.4, of resolving ions differing in composition by 13C CH/N using DF mass spectrometers. As demonstrated by the CNDs obtained from the chemical ionization high resolution mass spectra (CIHRMS) and the HRLVEIMS for the unfractinated
coal-derived distillate, this resolution problem effectively precludes, in general, the determination of low-levels of Z(NO, S) homologs in samples dominated by Z(H O, S) homologs using LVEI as the ionizing agent.

Allgood et al. found that charge-exchange reactions between C6H6+ and series of olefins and alkylbenzenes under CI conditions resulted in mass spectra containing essentially only molecular ions. The dependence of the relative molar sensitivities on molecular structure was found to be less then 10−15%. As expected, CE reactions between C6H6+ and alkanes and cycloalkanes were not observed allowing homologs of olefinic and aromatic compound types to be differentiated from homologs of these compound types. Hsu and Qian investigated CE reactions between CS2+ and a series of aromatic hydrocarbons. Electron beam energies that produced m/z 106 to m/z 91 ratios > 50:1 gave CS2 CE conditions that resulted in maximum ion signal magnitudes and minimum formation of fragment ions. However, the molecular structure dependence of sensitivity is greater for CS2 CE than for C6H6 CE because the increase in the alkyl carbon number from 6 to 13 in the −6(H) series was accompanied by an approximately 67% increase in the CS2 CE sensitivity. There are indications that an increase in the number of condensed aromatic rings results in a substantial increase in the sensitivity for CS2 CE of aromatic hydrocarbons, for example, the sensitivity for benzo[a]pyrene is about 3.3 times greater then the sensitivity for naphthalene.

Dzidic et al. developed and applied a GC low-resolution mass spectrometric method for hydrocarbon-type analysis of 350−850 °F (177−455 °C) distillates using Townsend discharge nitric oxide chemical ionization (TDNOCI). The NO+ produced under TDNOCI conditions distinguishes between homologs of hydrocarbon types by the occurrence of: (1) CE reactions with aromatics, (2) hydride extraction reactions with saturates and (3) addition reactions as well as both CE and hydride extraction reactions with olefins.

Dzidic investigated fluoride ion CI low-resolution MS with sample introductions using a direct probe as a method for determining naphthenic acids. Unfortunately the use of a quadrupole instrument precludes the resolution of isobaric carboxylate anions and, hence, the determination of CNDs. Fan reported on the characterization of naphthenic acids using negative ion FAB MS. The 2000 RP FAB spectra obtained from Xe bombardment of acid−triethanolamine matrices consisted of only (M−H)− ions. In contrast to this result, Grigsby et al. found that the positive ion FAB spectra of nitrogenous compounds and a base fraction from anthracene oil exhibited significant M++, (M+H)+, (M−H)+ and fragment ions.

6 QUALITATIVE ANALYSIS

6.1 Processing of High-resolution Mass Spectra

In general, an experimental high-resolution mass spectrum consists of pairs of data points consisting of peak positions and the sum of the signal magnitudes of the detected ions defining the peaks. The phrase “in general” is used because at least two commercial data acquisition systems afford the capability of storing “raw” data points, that is, the digitized signals from the mass spectrometer and the precisely defined times at which the signals were acquired. Peak positions in spectra acquired using a DF mass spectrometer commonly are the times for the peak centroids calculated from the data points defining the peaks. Peak positions in spectra acquired using a FTICR mass spectrometer are the frequencies of the peak centroids calculated from the frequencies across the peak obtained by fast Fourier transformation of the time-dependent signal from the FTICR instrument. The peak positions expressed as either times or frequencies must be converted to masses.

The time centroids of the peaks in spectra acquired exponentially using DF instruments are converted to highly accurate masses using a polynomial of the form, Equation (20)

\[ \ln(m/z) = A + Bt + Ct^2 + Dt^3 \]

The coefficients A−D in Equation (20) are determined by least squares analysis of the time centroids of known masses of five successive ions in a spectrum. A polynomial equation such as Equation (20) is used in place of Equation (14) because, as mentioned in section 4.2.2, Equation (14) is an inexact description of the rate of decrease of the magnetic field strength.

The frequency centroids of the peaks in spectra acquired using a FTICR mass spectrometer can be converted to masses using the relationship in Equation (21)

\[ m/z = \frac{a}{v} + \frac{b}{v^2} \]

which is exact in the limit of a pure quadrupolar electrostatic trapping potential. Values of the parameters a and b are determined by least squares analysis of the frequency centroids of known masses of three successive ions in a spectrum.

Concurrent acquisition of the spectrum of both know compounds and the sample being analyzed is one approach to establishing values of the masses and time centroids for determining the parameters in Equations (20) and (21). The mass defects of the reference ions must be considerably larger then those for the ions of unknown composition. Unfortunately, the traditional reference standards used with 70-eV electrons,
such as perfluorokerosenes, are not suitable for use with low-voltage electrons. Thus, mixtures consisting primarily of halogenated compounds have been used as mass calibrants.\(^\text{13,75,80}\) However, several problems attend the extensive use of chlorinated and/or brominated aromatic compounds. First, these compounds by their nature contain isotopically substituted molecules that result in the formation of isotopically substituted ions that are not germane to the calibration process. The presence of these molecules restricts the amount of sample that can be charged because the pressure range over which an ion source operates efficiently is necessarily restricted. Second, it has not been possible to achieve an optimum mass difference of approximately 14 u between successive molecular ions especially in the mass region above 300 u. Third, the insolubility of a number of these halogenated compounds complicates the preparation of reference blends. The compounds in Table 8 were adopted as calibrants at the Amoco Research Center in order to overcome several of these problems. It should be noted that solutions can be prepared that contain 26 of the 31 compounds. However, the issue of the lack of mass calibration standards above mass 630 remains to be resolved.

The use of ions formed from compounds in a sample either alone or in conjunction with ions formed from reference compounds is another approach to mass calibration. One caveat in the use of this approach is that the time centroids of the peaks used as reference standards must not have derived significant contributions from unresolved ions.

Schmidt and Sprecher used the mass measurement accuracy obtained from assigning formulas to mass converted peak centroids as a criterion for selecting sample peaks to be used in conjunction with reference peaks.\(^\text{79}\) The identification of a number of peaks resulting from the detection of \(Z(H)\) molecular ions containing carbon-13 rather than \(Z(NO_2)\) molecular ions is one of several results indicating that valid results were obtained in this instance. However, the ubiquitous problem of resolving ions that differ in composition by \(C_3/SH_4\) using DF mass spectrometers would in general preclude the use of sample peaks in mass converting time centroids in mass spectra of samples such as aromatic neutral, acidic and basic fractions that contain significant amounts of sulfur compounds. For example, the \(-6(H)\) series is the only homologous series of molecular ion peaks in the HRLVEIMS of aromatic neutrals that does not a priori reflect the detection of ions differing in composition by \(C_3/SH_4\). Hsu et al. have approached the problem by performing ring-number separations of aromatic neutral fractions prior to obtaining HRLVEIMS.\(^\text{86}\) At least in principle the ring number separation should significantly mitigate the \(C_3/SH_4\) resolution problem. For example,

\(^{b}\) C = carbon-12.

\(^{c}\) Compounds in solid mixture.

\(^{d}\) Fragment ion.

\(^{e}\) Isomer not critical.

HPLC separation should place the \((-10(S)\) series in the diaromatic fraction and the isobaric \((-20(H)\) series in the three-ring fraction. It should be noted when using this approach that the resolution in the separation decreases with increasing boiling point and can exhibit a dependency on the origin and history of the aromatic neutral fraction.

### 6.2 Resolving Power: Definitions

RP for magnetic deflection mass spectrometers is conventionally defined as the peak separation \((m/z)_{i+1} - (m/z)_{i}\) corresponding to a 10% valley between two equal-magnitude peaks resulting from detection of successive ion beams having mass-to-charge ratios \((m/z)_{i}\) and \((m/z)_{i+1}:

\[
RP(\text{DF/MS}) = \frac{(m/z)_{i+1} - (m/z)_{i}}{(m/z)_{i}} = \frac{(m/z)_{i}}{\Delta(m/z)} \quad (22)
\]
RP for ions of mass-to-charge ratio \((m/z)_i\) is conventionally defined in FTICR MS as

\[
RP(\text{FTICR/MS}) = \frac{(m/z)_i}{\Delta(m/z)}
\]  

(23)

where \(\Delta(m/z)\) is the full magnitude-mode mass spectral peak width at half-maximum peak height for an isolated peak.

Both definitions depend on peak shape. However, it is important to note that neither definition considers the dependence of peak separation and, hence, RP on the ratio of the signal magnitudes of adjacent peaks. Unfortunately, equal magnitude peaks are clearly the exception rather then the rule. Thus, the RP required to observe resolution of the majority of successive ion beams in the HRMS spectra of most samples exceeds values obtained from Equations (22) and (23) with the RP required to resolve successive ion beams increasing without limit as the ratio of the larger to smaller signal magnitude continues to increase. Therefore, let \(r\) be the ratio of the signal magnitudes \(SM_i\) and \(SM_{i+1}\) of successive beams calculated such that \(r \geq 1\), i.e. \(r = 1\) if \(SM_i = SM_{i+1}\), \(r = SM_i/SM_{i+1}\) if \(SM_i > SM_{i+1}\) and \(r = SM_{i+1}/SM_i\) if \(SM_{i+1} > SM_i\). Then for mass spectral peak shapes adequately described as Gaussian the dependence of RP on \((m/z)_i\), \(\Delta(m/z)\) and \(r\) can be shown to be\(^{121}\)

\[
RP = \frac{\log(20r)}{2\Delta(m/z)} 1 + \sqrt{\frac{\log(20)}{\ln 20}}
\]  

(24)

In Equation (24), it is understood that the peaks resulting from detection of successive ion beams are by definition resolved if the valley height is 10% of either peak height if \(r = 1\) and if the valley height is 10% of the lower magnitude peak if \(r > 1\). Alternatively, ion beams \(i\) and \(i+1\) are said to be resolved if the signal magnitudes at the intersection point of the two peak profiles are 5% of either peak height if \(r = 1\) or 5% of the lower magnitude peak if \(r > 1\). For Gaussian-shaped peaks it should be noted that the RP defined by Equation (23) is about 2.08 times greater then the RP defined by Equation (22).

6.3 Dependence of Resolving Power on the Differences in Composition, Mass-to-charge Ratios and Relative Abundances of Successive Ion Beams

The RP that is appropriate for an HRMS group-type analysis depends in part on the differences in the \(m/z\) values and the relative abundances of the isobaric ions that will be present in the mass spectra of a given sample. The difference in ion \(m/z\) values resulting from different ion compositions has been considered by a number of individuals.\(^{14,26,50,52,55,57,65,122,123}\) Table 9 lists differences in ion \(m/z\) values for various compositional differences consistent with the general formula \(C_aH_bN_cO_dS_e\) and the observation that the coefficients of the heteroatomic species of present interest will in general have values \(0 \leq a \leq 2, \ 0 \leq b \leq 4\) and \(0 \leq c \leq 2.65\).

The dependence of the \(m/z\) values of resolved ion beams having equal signal magnitudes on both RP and the \(m/z\) differences between them is illustrated in Figures 9 and 10 for RPs from 10 000 to 80 000 and \(\Delta(m/z)\) values from \(2 \times 10^{-3}\) to \(30 \times 10^{-3}\) u. Figures 9 and 10 show that the range of ion \(m/z\) values that can be resolved using RP values ranging from 10 000–80 000 exhibits a strong dependence on the difference in \(m/z\) values between successive ions. For example, Figures 9 and 10 show that increasing \(\Delta(m/z)\) from 2 to 10 to 30 millimass units (mmu) increases the resolvable range of \(m/z\) values from 200 to 800 to greater than 1800. The rate of increase in the \(m/z\) value of resolved ion beams at a given RP is seen to increase dramatically with increasing \(\Delta(m/z)\). For example, Figures 9 and 10 reveal that the upper limit of the mass range of resolved ions at 40 000 RP increases from 80 to 720 as \(\Delta(m/z)\) varies from 2 to 18 mmu. However, Figure 9 shows that increasing the RP to 80 000 has only a marginal effect on the resolvable mass range for ions having \(\Delta(m/z)\) differences less then 6 mmu.

The dependence of the RP required to resolve doublets on both the ion compositions and relative abundances are illustrated for a range of \(\Delta(m/z)\) values in Table 10. Column 4 lists the \(\Delta(m/z)\) values resulting from the compositional differences in column 3 between the doublets having the compositions shown in column 2. Values of the RP required for resolution of the members of each doublet having equal signal magnitudes and the maximum \(m/z\) value at which each doublet will be resolved are listed in columns 5 and 6, respectively. Inspection of Equation (24) reveals that the relative abundance of resolved ions increases with decreasing \(m/z\) at a given RP. The values in columns 7 and 8 in Table 10 illustrate the dependence of the relative abundance of resolved ions on ion mass for the RPs in column 5. For example, a RP of 6438 is predicted to resolve \(\sim 26(H)\) and \(\sim 12(H)\) ions having relative abundances \(\geq 50\) at \(m/z\) values \(\leq 480\) and \(\geq 100\) for \(m/z \leq 4 66\). Table 10 illustrates the ubiquitous problem of resolving ions that differ in composition by \(C_3/SH_4\) and various isotopically substituted ions.

6.4 Mass Analyzers and the Resolution of Ion Beams

6.4.1 Double Focusing Magnetic Instruments

Large geometry state-of-the-art DF instruments can be used to acquire HRLVEIMS exhibiting adequate ion intensities from about \(m/z\) 100 to about \(m/z\) 650 at RPs ranging up to about 60 000, depending upon factors such as the magnitude of the total aberrations,

</table>

$^a$ The mass difference is the absolute value of the difference $(m/z)_2 - (m/z)_1$ for the formula differences $F_2/F_1$.  

Figure 9 Mass-to-charge ratios of resolved ion beams having equal signal magnitudes as a function of RP and mass-to-charge ratio differences of $2 \times 10^{-3}$, $6 \times 10^{-3}$ and $10 \times 10^{-3}$ u.
which for a given instrument determines the ion source and collector slit widths required, the rates of ion production that can be achieved with commercial electron impact sources operated at low voltage, the ranges in both the masses and the amounts of the compounds in a sample and the amount of sample that can be introduced into a DF mass spectrometer ion source. If we assume that singly charged ions having unit relative abundances are to be resolved at mass 650 then ions having compositional differences resulting in mass differences greater than 65, 32.5, 16.3 and 10.8 mmu will be resolved in spectra acquired at 10,000, 20,000, 40,000 and 60,000 RP, respectively. Doublets with mass differences less than these values will not be resolved over the entire mass range. For example, resolution of doublets 22–65 listed in Table 9 should be realized in LVEI mass spectra acquired at 40,000 RP. However, doublets such as $^{13}$C/CH and C$_4$/H$_2$NO$_2$ (numbers 6 and 14 in Table 9) will be resolved up to $m/z$ values of only about 180 and 344.

The presence of unresolved doublets must be taken into account in the processing of HRLVEIMS in order to avoid introducing significant errors into the analytical results. For example, the signal magnitudes of odd mass peaks potentially corresponding to unresolved $^{13}$CH/N doublets need to be corrected for contributions from the ion abundances of the appropriate peak at one mass lower in order to avoid overestimating the contribution of nitrogenous homologs to the sample. Failure to consider that odd mass peaks correspond to unresolved $^{13}$C/CH doublets could result in the erroneous identification of homologs of types such as Z(NO$_2$) in a sample rather than homologs of fragment ion types such as Z(H) in a spectrum.

A number of indirect approaches to circumventing this lack of spectral resolution have been developed. One approach involves extrapolations based upon a combination of differences in the initial carbon numbers of unresolved molecular ions and the distillation characteristics of their precursor homologs. Unfortunately a detailed description has apparently never been published. Deconvolution of peaks derived from data discreetly acquired during a scan is another approach to enhancing resolution. The deconvolution method described

by Van Katwijk\(^{[56,57]}\) is directly applicable to the processing of spectra acquired by exponential variation of the magnetic field strength. A method developed by Scheppele and Nutter analyses a HRMS for the presence of unresolved peaks, corrects the spectrum for contributions of ions containing either carbon-13 or sulfur-34 or both and assigns probable formulas to the mass and intensity corrected peaks. The method has been described in detail by Gaun et al.\(^{[92]}\) A related approach to processing unresolved peaks has been described by Roussis.\(^{[90]}\)

6.4.2 Fourier Transform Ion Cyclotron Mass Spectrometers

As seen in Figures 9 and 10, in Table 10 and discussed in section 6.3, resolution of a number of important doublets requires RPs that exceed the capabilities of DF instruments. The instrumental resolution of doublets such as C\(_{3}\)/SH\(_{4}\), C\(_{3}\)/CH and C\(_{3}\)/CH/N would significantly benefit HRMS-type analyses by increasing the reliability of the results and significantly reducing the time for spectral processing. It is thus important to note that several authors have demonstrated the resolution of such doublets in the mass spectra of samples of interest using FTICR mass spectrometers.\(^{[91,92,97]}\) In addition, the errors in mass measurement were typically 1 ppm or less.\(^{[92,97]}\) The mass range over which spectra exhibiting resolutions exceeding 300 000 (based upon the Full Width Half Maximum (FWHM) definition) can be acquired was significantly increased and, hence, the time required to cover the complete mass range of a sample was diminished by replacement of the three Telsa magnet\(^{[92]}\) with a 5.6 Telsa magnet.\(^{[96,97]}\)

7 QUANTITATIVE ANALYSIS

Cross-sections for ionization are of fundamental significance to quantitative MS because they provide the basis for describing the relationship between the total ionization and the concentration of neutral species in the region of ionization. However, the relationship between ion signal magnitudes and the composition of a mixture uses the concept of sensitivity. The relationship between cross-sections and sensitivities for EI is developed in sections 7.1 and 7.2 in order to provide a precise definition and a clear understanding of the concept of sensitivities. Formulas for calculating CNDs and a number of chemical properties from these distributions are derived in section 7.3. The effect of isomers on the quantitation of homologs is also addressed. Ionization sensitivities are an important factor in determining the accuracy of CNDs. However, the published literature contains only a limited number of studies involving the determination of low-voltage EI sensitivities for ionization of aromatic compounds.\(^{[6,8,10,11,13,16,19,22,23,26,34,37,38,47,72,80,97,125 – 127]}\) Moreover, few attempts at developing correlations that express the functional dependence of LVEI sensitivities on molecular structure quantitively have been
Development of these correlations is essential in order to predict values for LVEI sensitivities because the number of organic compounds for which LVEI sensitivities can be determined comprises an unacceptably small subset of the compounds either known or thought to be present in distillates of present interest. Qualitative correlations of the dependence of LVEI sensitivities on molecular structure have been published and extensively reviewed. Unfortunately, these correlations do not allow the prediction of LVEI sensitivities. Consequently, the following approach was adopted in addressing the issue of developing a database of LVEI sensitivities. Fundamental phenomena that affect the shape of the ionization efficiencies in the threshold region are reviewed in section 7.4. The practical consequences of these phenomena on experimental LVEI ion abundances are considered in section 7.5. Section 7.6 addresses the prediction of LVEI sensitivities from EI and photoionization cross-sections. The reproducibility of sensitivities for LVEI of aromatic hydrocarbons are reviewed and discussed in terms of values predicted from relative electron-impact ionization probabilities assuming a linear threshold law for ionization in section 7.7.

### 7.1 Electron Ionization Cross-sections

Total ionization cross-sections can be calculated from total ion currents determined without mass analysis of the ion beams. Consider compound $k$ with an internal energy defined by temperature $T$. Values of the total cross-section for ionization of compound $k$ by electrons with an energy $V$ electron volts are given by Equation (25)

$$\sigma_{k,T,V} = \left(\frac{TIC_{k,T,V}}{n_{\text{tot},k}}\right)\text{Vol}^{-1}L_d$$

where $TIC_{k,T,V}$ is the total ion current, $L_d$ is the ionizing pathlength in cm and $n_{\text{tot},k}\text{Vol}^{-1}$ is the number of molecules per cubic centimeter in the ion source. Thus, the cross-section has units of cm$^2$ molecule$^{-1}$.

The cross-sections for ionization of the isotopically most abundant molecules of a given compound are of interest because the $m/z$ values and signal magnitudes of the isotopically most abundant molecular ions rather than total ion signal magnitudes are of analytical significance. If $k(1)$, $k(2)$, $k(3)$, $k(l)$ designates the order of the variously isotopically substituted molecules of compound $k$ according to decreasing natural abundance, then the number of each of them is $n[k(1)]$, $n[k(2)]$, $n[k(3)]$, $n[k(l)]$. If EI of the isotopically most abundant molecules results in the formation of molecular ($j = 1$) and fragment ($j = 2, 3, 4, \ldots, m$) ions then the cross-section for ionization of the isotopically most-abundant molecules of compound $k$ is given by Equation (26)

$$\sigma_{k(1),T,V} = \sum_{j=1}^{m} PM(j)_{k(1)}GM(j)_{k(1)}N_{k(1)}\text{Vol}^{-1}I_dR_SM$$

In Equation (26), the numerator is the signal magnitude of the $j$th isotopically most-abundant ion formed from ionization of compound $k(1)$ in volts, $PM(j)_{k(1)}$ represents the probability that the $j$th ion from $k(1)$ will exit the ion source and be transmitted through the mass analyzer and be detected, $GM(j)_{k(1)}$ designates the detector gain for this ion and $R_s$ and $SM$ designate the resistor in the ion-current amplifier and the experimental ion signal magnitude per volt of signal from the detector system, respectively.

We now express the number of isotopically most-abundant molecules $n_{k(1)}$ as a function of the total number of moles of compound $k$, $N_{\text{tot},k}$. The number of isotopically most-abundant molecules is given by Equation (27)

$$n_{k(1)} = FP_{k(1)}N_{\text{tot},k}N_A$$

where $FP_{k(1)}$ is the fractional percentage abundance of the isotopically most-abundant molecules and $N_A$ is Avogadro’s number. Values of $FP_{k(1)}$ can be obtained to acceptably high levels of accuracy from Equation (28)

$$FP_{k(1)} = \frac{\sum_i a_i b_{i,j}^{j(i)}}{\sum_j b_{i,j}^{j(i)}}$$

where $a_i$ represent the number of the $i$th element and $b_{i,j}$ denotes the number of the $j$th isotope of the $i$th element in a formula. The symbols and values for $i$ and $j$ are defined for terms of elements and isotopes in Table 11.

Substituting Equation (27) into Equation (26), we obtain the following expression for the cross-section for ionization of the isotopically most-abundant molecules of compound \( k \) expressed as a function of the signal magnitudes of the molecular ion and fragment ions formed from ionization of molecules \( k(1) \), the total moles of compound per cubic centimeter of the ion source, the ionizing electron current, the ionizing pathlength, the detector gain and the probability that a molecular ion will exit the ion source and be transmitted through the mass analyzer and be detected, Equations (29) and (30)

\[
\sigma_{k(1),T,V} = \frac{1}{\kappa} \sum_{j=1}^{m} \frac{SM(j)k(1),T,V}{PM(j)k(1)} \times \frac{GM(j)k(1)}{FP_{k(1)}} N_{tot,k}
\]

where

\[
\kappa = R_s SM_N A d V \text{cm}^{-1}
\]

The total cross-section for ionization of compound \( k \) by electrons possessing energy \( V \) is a linear combination of the cross-sections for ionization of the various isotopically substituted species weighted by their fractional percentage abundance, that is, Equation (31)

\[
\sigma_{k,T,V} = \sigma_{k(1),T,V} FP_{k(1)} + \sigma_{k(2),T,V} FP_{k(2)} + \sigma_{k(3),T,V} FP_{k(3)} + \cdots + \sigma_{k(m),T,V} FP_{k(m)}
\]

Since the Born–Oppenheimer approximation is valid for the range of energies of present interest, the potential energy hypersurfaces for both ionic and neutral species are independent of isotopic substitution. However, ionization cross-sections could be subject to isotope effects because the vibrational and rotational energy levels associated with these electronic states are isotope dependent. In this regard, the ionization cross-sections for small deuterated polyatomic molecules were subject to deuterium isotope effects ranging from about 1.01 to about 1.05. (128,129) Deuterium and heavy atom such as carbon-13 isotope effects would be expected to be considerably smaller for large polyatomic molecules. Thus, Equation (31), reduces to Equation (32)

\[
\sigma_{k,T,V} = \sigma_{k(1),T,V}
\]

for the condition that isotope effects on ionization cross-sections are less than the experimental uncertainties in these values.

7.2 Low-voltage Ionization Cross-sections and Ionization Sensitivities

In order to derive the relationship between LVEI cross-sections and sensitivities we separate the RHS of the equation obtained from combining Equations (29) and (32) into terms for molecular and fragment ions and rearrange the result to obtain

\[
(\sigma_{k,T,V}) FP_{k(1)} = \frac{SM(1)k(1),T,V}{\kappa PM(1)k(1)GM(1)k(1)} N_{tot,k} + \frac{1}{\kappa}
\]

\[
\times \sum_{j=2}^{m} \frac{SM(j)k(1),T,V}{PM(j)k(1)GM(j)k(1)} N_{tot,k}
\]

If the cross-section for ionization of compounds by low-voltage electrons are either known or assumed to be dominated by molecular ions then the second term in the RHS of Equation (33) can be neglected. For either situation, Equation (33) reduces to

\[
(\sigma_{k,T,V}) FP_{k(1)} = \frac{SM(1)k(1),T,V}{\kappa PM(1)k(1)GM(1)k(1)} N_{tot,k}
\]

The RHS of Equation (34) is the signal magnitude for the isotopically most-abundant molecular ion for a given value of the concentration of the precursor homolog in the ion source, the ionizing electron current, the ionizing pathlength and both the detector gain and the ion-source extraction and analyzer transmission probabilities for these ions. Thus, a solution of Equation (34) is by definition a mass spectrometric response factor, termed an ionization sensitivity, for the \( k \)th compound. Thus, the sensitivity for ionization of the \( l \)th compound per mole of the \( k \)th compound by low-voltage electrons with energy \( V \), termed the mole sensitivity, has the units square centimeters per mole and is by definition

\[
S(\text{mol})_{k,T,V} = \frac{SM(1)k(1),T,V}{\kappa PM(1)k(1)GM(1)k(1)} N_{tot,k}
\]

Combining Equations (34) and (35) we obtain

\[
S(\text{mol})_{k,T,V} = (\sigma_{k,T,V}) FP_{k(1)}
\]

Equation (36) reveals that the mole sensitivities required for calculating CNDs from molecular ion signal magnitudes could be obtained from total ionization cross-sections provided that the contribution of fragment ions to the total ionization is either minimal or known.

As discussed in sections 7.4 and 7.5 the ionization cross-section is a rapidly changing function in the threshold region. Consideration of Equations (25), (26) and (35) in terms of this fact and other factors such as the performance characteristics of conventional electron ion sources, the focusing of ion beams and the ion statistics accounts for the difficulties that are often experienced in obtaining satisfactorily reproducible ionization efficiency curves and absolute values of cross-sections and mole sensitivities in the threshold region. The influence of these factors can be minimized by determining relative
cross-sections and relative mole sensitivities. These values can be converted to absolute values given the value for the reference compound. It should be noted that the use of relative rather than absolute mole sensitivities expedites the determination of CNDs because the necessity of determining the absolute sensitivity a mass spectrometer routinely is abrogated.

Let \( \sigma_{rel,k,T,V} \) and \( S(mol)_{rel,k,T,V} \) designate the cross-section and mole sensitivity, respectively, for ionization of the \( k \)th compound relative to the corresponding quantities for ionization of the reference compound ref, where \( T \) and \( V \) designate the gas temperature and the ionizing energy, respectively. Let \( \text{ref}(1) \) represent the isotopically most-abundant neutral and ionic reference species. Thus, the relative cross-sections and relative mole sensitivities are, Equations (37), (38) and (39)

\[
\sigma_{rel,k,T,V} = \frac{TIC_{k,T,V}}{TIC_{\text{ref},T,V}} \frac{N_{tot,ref}}{N_{tot,k}} \tag{37}
\]

\[
\sigma_{rel,k,T,V} = \frac{SM(1)_{k(T,V)}}{SM(1)_{\text{ref}(1),T,V}} \frac{N_{tot,ref}}{N_{tot,k}} \frac{PM(1)_{\text{ref}(1)}}{PM(1)_{k(1)}} \times \frac{GM(1)_{\text{ref}(1)}}{GM(1)_{k(1)}} \times \frac{FP_{\text{ref}(1)}}{FP_{k(1)}} \tag{38}
\]

\[
S(mol)_{rel,k,T,V} = \frac{SM(1)_{k(T,V)}}{SM(1)_{\text{ref}(1),T,V}} \frac{N_{tot,ref}}{N_{tot,k}} \frac{PM(1)_{\text{ref}(1)}}{PM(1)_{k(1)}} \times \frac{GM(1)_{\text{ref}(1)}}{GM(1)_{k(1)}} \tag{39}
\]

Equation (40) expresses relative sensitivities on a gram basis as function of molecular ion signal magnitudes and the grams of each compound in the mixture, \( g_{tot,k} \), and the grams of the reference compound, \( g_{tot,ref} \)

\[
S(g)_{rel,k,T,V} = \frac{SM(1)_{k(T,V)}}{SM(1)_{\text{ref}(1),T,V}} \frac{g_{tot,ref}}{g_{tot,k}} \frac{PM(1)_{\text{ref}(1)}}{PM(1)_{k(1)}} \times \frac{GM(1)_{\text{ref}(1)}}{GM(1)_{k(1)}} \tag{40}
\]

Relative mole sensitivities are converted into relative gram sensitivities using Equation (41)

\[
S(g)_{rel,k,T,V} = S(mol)_{rel,k,T,V} \frac{(M_r)_{ref}}{(M_r)_k} \tag{41}
\]

where \((M_r)_{ref}\) and \((M_r)_k\) are the relative molecular masses of the reference compound and compound \( k \), calculated from the atomic weights of their constituent elements, respectively.

### 7.3 Calculation of Carbon Number Distributions and Chemical Properties

Consider the ionization of the \( j \)th homolog in the \( i \)th specific \( Z \) series at temperature \( T \) by electrons of voltage \( V \). The \( j \)th homolog may consist of \( 0, 1, 2, 3, \ldots \) \( l \) isomers. For the sake of simplicity, the notation for this homolog is taken to be \( Z_{i,j,l} \) and is illustrated in Table 12 for the first three members of the \(-6(\text{H})\) homologous series.

Consider a sample containing the four compounds shown in Table 12. The first and second homologs consist of only one compound each. However, the third homolog is composed of four isomers. Following conventional practice, we assume that the detector gains and the ion-source extraction/analyzer transmission probabilities are the same for the molecular ions of the compounds listed in Table 12. Thus, using absolute rather than relative sensitivities, the number of moles of the first and second homologs benzene and toluene are, Equations (42) and (43)

\[
N_{tot,Z_{-4,1,0}} = \frac{SM(78)_{Z_{-4,1,0},T,V}}{S(mol)_{Z_{-6,1,0},T,V}} \tag{42}
\]

and

\[
N_{tot,Z_{-4,2,0}} = \frac{SM(92)_{Z_{-4,2,0},T,V}}{S(mol)_{Z_{-6,2,0},T,V}} \tag{43}
\]

respectively. Since the third homolog consists of four isomers, the number of moles of this homolog is given by Equation (44)

\[
N_{tot,Z_{-4,3,4}} = \frac{SM(106)_{Z_{-4,3,1},T,V}}{S(mol)_{Z_{-6,3,1},T,V}} + \frac{SM(106)_{Z_{-4,3,2},T,V}}{S(mol)_{Z_{-6,3,2},T,V}} + \frac{SM(106)_{Z_{-4,3,3},T,V}}{S(mol)_{Z_{-6,3,3},T,V}} + \frac{SM(106)_{Z_{-4,3,4},T,V}}{S(mol)_{Z_{-6,3,4},T,V}} \tag{44}
\]

Molecular ion mass-to-charge ratios and signal magnitudes are the experimentally accessible quantities in a HRMS homolog analysis. Since the first and second \(-6(\text{H})\) homologs correspond to the presence of only one compound each, Equations (42) and (43) can be solved to obtain values for the number of moles of benzene and toluene in the mixture. In contrast, solving Equation (44) to obtain the number of moles of the third \(-6(\text{H})\) series homolog would require the signal magnitudes of the four

</table>
$C_8H_{10}$ molecular ions rather then the sum of these signal magnitudes which is the experimentally accessible quantity $SM_{(106)_{exp},T.V}$. Therefore, a homolog mole sensitivity which is a value bounded by the least and greatest mole sensitivities for the set of isomers is substituted for the four sensitivities in Equation (44) in order to obtain a value for the number of moles of the third homolog. Hence, Equation (44) reduces to Equation (45)

$$N_{tot,Z_{i+3}}^{Z_{i+3}} = \frac{SM_{(106)_{exp},T,V}}{S(mol)_{Z_{i+3},T,V}}$$

(45)

The sensitivities used in calculating quantitative distributions are, in general, values for homologs rather then values for specific compounds. The magnitudes of the error so introduced into the quantitative results are a complex function of variables such as the difference between the assumed and correct sensitivity values for the actual isomeric mixture, the signal magnitude of the homolog molecular ion, the effect of mass discrimination on the molecular-ion signal magnitudes and the number of homologs of the compound types present in the sample.

For the general case, consider a distillate sample containing 1, 2, 3, $i$ compound types. Each compound type consists of 1, 2, $j$ homologs. The mole percentage of the $j$th homolog in the $i$th specific $Z$ series is

$$MP_{Z_{i,j}} = \frac{N_{tot,Z_{i,j}}^{Z_{i,j}}}{\sum_j N_{tot,Z_{i,j}}^{Z_{i,j}}} \times 100$$

(46)

where for the sake of simplicity $Z_{i,j}$ has been substituted for notation $Z(N_{i,j}O_{j}S_{i,j})$. Generalizing the result obtained from substituting Equations (42), (43) and (45) into Equation (46), we obtain Equation (47) for calculating mole-percentage CNDs from the signal magnitudes of the isotopically most-abundant molecular ions

$$MP_{Z_{i,j}} = \frac{(SM_{Z_{i,j},T,V})/(S(mol)_{rel,Z_{i,j},T,V})}{\sum_i \sum_j (SM_{Z_{i,j},T,V})/(S(mol)_{rel,Z_{i,j},T,V})} \times 100$$

(47)

Weight-percentage CNDs can be calculated by solving Equation (48)

$$WP_{Z_{i,j}} = \frac{(SM_{Z_{i,j},T,V})/(S(g)_{rel,Z_{i,j},T,V})}{\sum_i \sum_j (SM_{Z_{i,j},T,V})/(S(g)_{rel,Z_{i,j},T,V})} \times 100$$

(48)

or from mole percentage CNDs using Equation (49)

$$WP_{Z_{i,j}} = \frac{MP_{Z_{i,j}}(M_r)_{Z_{i,j}}}{\sum_i \sum_j MP_{Z_{i,j}}(M_r)_{Z_{i,j}}} \times 100$$

(49)

where $(M_r)_{Z_{i,j}}$ is the relative molecular mass of the $j$th homolog in the $i$th specific $Z$ series. CNDs on a weight-percentage basis can also be obtained using Equation (50)

$$WP_{Z_{i,j}} = \frac{[(SM_{Z_{i,j},T,V})/(S(mol)_{rel,Z_{i,j},T,V})] \times (M_r)_{Z_{i,j}}}{\sum_i \sum_j [(SM_{Z_{i,j},T,V})/(S(mol)_{rel,Z_{i,j},T,V})] \times (M_r)_{Z_{i,j}}} \times 100$$

(50)

Aczel and Lumpkin have demonstrated the routine calculation of a significant number of chemical properties from CNDs,(38,52,53) The properties calculated include the average carbon number, the average molecular weight and the elemental analysis for each compound type and for the sample. In addition to these properties, Schmidt et al. reported calculating average specific $Z$ values and values of $f_a$, that is, the fraction of the total carbon that is aromatic.(75) Aczel and Lumpkin have also shown that CNDs can be used to calculate distillation characteristics for a sample and to generate CNDs for the compound types expected to be present in the predicted narrow-boiling distillate cuts.(32) Unfortunately many of the essential details of the method have not been described. Chemical properties for narrow boiling distillate cuts should be predictable from the CNDs for these fractions. Scheppele and Greenwood were able to draw conclusions concerning the occurrence of reaction networks in the hydrotreating of anthracene oil from the CNDs for the feed and products.(66)

In regard to such calculations, the average relative molecular mass for a specific $Z$ series, $(\bar{M})_{Z_{i}}$, the average relative molecular mass for the sample, $\bar{M}$, the average carbon number for a specific $Z$ series, $\bar{n}_{Z_{i}}$, and the average carbon number for the sample, $\bar{n}$, are solutions to Equations (51–54), respectively

$$\bar{M}_{Z_{i}} = \frac{\sum_i MP_{Z_{i,j}}(M_r)_{Z_{i,j}}}{\sum_i TMP_{Z_{i,j}}(\bar{M})_{Z_{i}}_{j}}$$

(51)

$$\bar{M} = \frac{\sum_i TMP_{Z_{i,j}}}{100}$$

(52)

$$\bar{n}_{Z_{i}} = \frac{\sum_i MP_{Z_{i,j}}n_{Z_{i,j}}}{\sum_i TMP_{Z_{i,j}}}$$

(53)

$$\bar{n} = \frac{\sum_i TMP_{Z_{i,j}}\bar{n}_{Z_{i,j}}}{100}$$

(54)

where, Equation (55)

$$TMP_{Z_{i,j}} = \sum_i MP_{Z_{i,j}}$$

(55)
Let $Y_u$ denote the presence of $u$ atoms of element $Y$ in a formula and let $A(Y)$ represent the atomic weight of element $Y$. The weight percentage of element $Y$ in a sample is thus

$$ WP(Y) = A(Y) \sum_i \sum_j \frac{WP_{Z_i} u_{Z_i}}{(M_r) Z_i} \tag{56} $$

where $(M_r) Z_i$ is the relative molecular mass of a homolog calculated from the atomic weights of its constituent elements.

### 7.4 Fundamental Phenomena

Consider compound $k$ with an internal energy defined by temperature $T$. The cross-section for its ionization by electrons having a nominal energy $V$ is given by

$$ \sigma_{k,T,E} = \sum_k \int_{-\infty}^{+\infty} K_k (V - IP_k) m(V - IP_k) \, dV \tag{57} $$

where $K_k$ are the probabilities for transitions from the ground state of the neutral molecule to the various $k$ states of the ion having ionization potentials $IP_k$. $Th(V - IP_k)$ are the threshold laws for the transitions and $m(V - IP_k)$ is the energy distribution in the ionizing beam.\(^{130-132}\) Equation (57) includes contributions of single-direct ionization, multiple-direct ionization and autoionization to the cross-section. The contribution of multiple-direct ionization to the cross-section for ionization in the threshold region should be negligible for compounds of present interest. Unfortunately, very little definitive evidence exists concerning the contribution of electron-induced auto-ionization to the total ionization in the threshold region for these compounds. Therefore, we necessarily assume that single-direct ionization dominates the cross-section for electron-induced ionization of compounds of present interest. For this case, several theoretical analyses predict a value of one for the exponent $\psi$ in the threshold law.\(^{130-132}\) Ionization efficiencies obtained for polyatomic compounds and radicals using energy-resolved electron beams are consistent with a linear or an apparently linear threshold law, that is, if the threshold law is nonlinear, the region of nonlinearity falls within the energy resolution of the electron beam (0.07 – 0.08 eV).\(^{133-136}\)

The assumption that the mass spectrum of a polyatomic molecule results from competing and consecutive unimolecular reactions of internally excited molecular ions led to the development of the quasi-equilibrium theory (QET).\(^{140,141}\) Briefly, The RRKM (Rice–Ramperger–Kassel–Marcus) rate constants, $k(E)$, for each unimolecular decomposition with a barrier height $E_o$ are calculated as a function of the internal energy $E$ of the molecular ion. These rate constants and the reaction times are used to compute a breakdown graph that describes the yield of all ions in the reaction network quantitatively as a function of the internal energy of the molecular ion. Convolution of the breakdown graph with both the internal energy distribution function ($P(E)$) and the electron energy distribution function (EED) yields the mass spectrum. The $P(E)$ corresponds to the convolution of the energy deposition function ($P(ED)$) and the Boltzmann function describing the thermal energy distribution of the neutrals prior to ionization. The $P(ED)$ describes the probability of producing a molecular ion possessing an internal energy $E$ as a function of the energy of the ionizing electron. Thus, $P(ED)$ depends upon the Franck–Condon factors for electronic transitions from the various vibrational levels of the ground state of a molecule to the different vibrational levels of the various electronic states of the ion and upon the threshold law. The threshold law describes the probability of transferring an energy $E + IP_k$ to the molecular ion as a function of the energy of the incident electron.

### 7.5 Practical Consequences of Fundamental Phenomena

Both the fundamental factors considered in the previous section and the operating characteristics of conventional electron sources have an impact on the practical application of low-voltage electrons as an ionizing medium. The threshold region for compounds of interest extends from about 6 eV to approximately 13 eV.\(^{142}\) Equation (57) reveals that the cross-sections for ionization of these compounds by electrons having nominal energies in this range and energy distributions $m(V - IP_k)$ depend upon the magnitudes of both the Franck-Condon factors for accessible transitions and the differences $V - IP_k$. For a given value of the ionizing energy, the function $V - IP_k$ will vary significantly in the threshold region as the ionization potential decreases. This conclusion is substantiated by the values in columns 3 and 4 of Table 13 for the compounds and ionization potentials listed in columns 1 and 2, respectively. Since the ionization potentials for aromatic hydrocarbons are lower than for saturated hydrocarbons, the threshold laws in column 5 are seen to be considerably larger for the former than for the latter. The values in columns 5 and 6 also show that the function $V - IP_k$ increases with increasing aromaticity. A decrease in the electron energy by 3 eV is seen in column 7 to lead to a marked decrease in the magnitude of the threshold law for the three aromatic hydrocarbons.

The previous discussion reveals that the production of large numbers of molecular ions is facilitated by large values of $V - IP_k$. However, the formation of molecular ions with insufficient energy to undergo decomposition at a given nominal value of the electron energy reflects the kinetics of fragmentation, the internal energy of the
molecular ion and the EED. For a given value of \( V \), the range of internal excitation energies available to the molecular ion is \( 0 \leq E \leq V - \text{IP} \). The RRKM rate constants, \( k(E) \), increase rapidly as \( E \) rises above \( E_{0.1} \), where \( E_{0.1} \) is the barrier height for the lowest energy fragmentation reaction. Thus, production of high yields of stable molecular ions relative to fragment ions requires that only a relatively small fraction of the electrons in the beam have energies in excess of \( \text{IP} + E_{0.1} \).

The second derivative of the ionization efficiency (SDIE) for formation of an ionized atom in its ground electronic state reduces to the EED reversed with respect to energy provided that ion formation involves single direct ionization obeying a linear threshold law. \(^{132} \) A SDIE for xenon obtained by numerical differentiation of an experimentally determined first derivative of the ionization efficiency (FDIE) of xenon in the threshold region is reproduced in Figure 11. \(^{143} \) The FDIE curve was obtained with a clean ion source and with the electron shield at zero potential with respect to the filament and with the extraction-plate potentials near the block potential to minimize the effect of contact potentials on the EED. The trap current was 20 \( \mu \)A to minimize space charge. The second maximum in the SDIE curve in Figure 11 which occurs at 12.8 \( \pm \) 0.1 eV is caused by the 6d autoionizing state. \(^{144} \) In agreement with theory, \(^{132} \) the SDIE for formation of Xe\(^+\) in the \( ^2P_{3/2} \) state is seen to correspond to a reversed Maxwellian distribution having a FWHM of 0.50 eV.

As seen in Figure 11, a significant probability exists that the ionizing beam will contain electrons having energies ranging from the nominal value up to about the nominal value plus 1.4 eV. Thus, molecular ions would be observed at nominal electron energies of approximately \( \text{IP} \pm 1.4 \) eV. Furthermore, the internal energies of the molecular ions can be increased over those present in the neutral precursor by amounts ranging from \( V - \text{IP} \) up to \( V - \text{IP} + 1.4 \) eV. Thus, for \( V = \text{IP} \) the EED shown in Figure 11 could produce molecular-ion decomposition reactions having \( E_{0.1} \leq 1.4 \) eV.

A number of experimental phenomena can increase the spread of electron energies in the ionizing region. For example, the use of 0.030inch (0.0762 cm) rather than 0.020inch (0.0508 cm) rhenium ribbon increased the FWHM of the EED from 0.42–0.55 eV to 0.63–0.74 eV. \(^{143} \) An increase in the contamination of the ion source necessitates an increase (decrease) in the voltage applied to the repeller (extractor) electrodes which results in an increase in the FWHM of the EED. For example, SDIE curves for Xe having FWHM values in excess of 1 eV were obtained for contaminated ion sources. The FWHM of the EED is sensitive to the potential on the electron trap due to field penetration. For example, operation of a CEC 21-110B mass spectrometer at low-ionizing energies required modification of the ion source circuitry because penetration of the field resulting from the high fixed potential applied to the trap into the ionizing region sufficiently broadened the distribution of electron energies so that molecular ions

of benzene were observed at nominal electron energies below 1 eV.

Samples of interest generally require inlet and ion-source temperatures of 250 °C or greater. At these temperatures, the average thermal energy may attain considerable values for large molecules and the distribution of these energies will encompass a considerable range of energies because of the large number of degrees of freedom over which the thermal energy may be distributed. For example, at 300 °C the average thermal energy of propane is ca. 0.3 eV and the FWHM of the Boltzmann distribution is approximately 0.3 eV.\(^{(145)}\) At 327 °C the calculated thermal energy distribution for hexane has an average value of ca. 0.55 eV and extends from slightly greater than 0 eV up to ca. 1.5 eV.\(^{(146)}\) The calculated average thermal energy of 2-phenyl-2-methylpropane at this temperature is about 0.8 eV and the calculated distribution ranges from 0.2 to approximately 1.8 eV.\(^{(147)}\) Since the thermal-energy content of the neutral species is fully effective in determining the kinetics of ion decompositions, the yield of fragment ions relative to molecular ions and the degree to which the ionization efficiency curves for these ions asymptotically approaches the energy axis increases with temperature for a given compound and with molecular size for a given temperature. For example, the thermal shifts of the ionization curves for a series of alkanes range from 0.10–0.24 eV as the temperature is raised from 28–142 °C.\(^{(148)}\)

Appearance potentials for formation of fragment ions from saturated compounds are only a few tenths of a volt above their ionization potentials.\(^{(142)}\) This fact together with the phenomena discussed above precludes the use of low-voltage electrons as the ionizing agent for performing homolog-type analysis of saturated hydrocarbons because of low molecular-ion signal magnitudes. Since the appearance potentials for fragment ions from aromatic compounds are generally greater than about 1–1.5 eV above their ionization potentials,\(^{(142)}\) an electron energy can usually be selected that results in acceptably large molecular ion to fragment ion signal magnitude ratios.

### 7.6 Electron Impact Ionization and Photoionization Cross-sections

Total ionization cross-sections have been determined for a number of organic compounds.\(^{(129,149–157)}\) Unfortunately, these cross-sections have only limited applicability with regard to predicting LVEI sensitivities for two reasons. First, except for benzene\(^{(129,149,150,153)}\) and a series of its alkylated homologs\(^{(129,153)}\) the cross-sections are for the ionization of compounds that are not of interest here. Second, the majority of cross-sections are for ionizations using 70–75 eV electrons. Harrison et al.\(^{(129)}\) observed that the 75-eV cross-sections for ionization of benzene and its alkylated homologs increase with increasing carbon number up to a carbon number of nine. Within the limits of data precision, the cross-sections were found to be both carbon number- and isomer-independent for C\(_9\) and C\(_{10}\) homologs. In contrast, Alberti et al. observed that the 75-eV cross-sections for benzene and n-alkylated homologs containing up to 15 carbons increased with increasing alkyl carbon number by a constant amount per CH\(_2\) group.\(^{(153)}\) Munson et al. also observed that the 70-eV cross-sections for −6(H) series homologs containing 2–10 alkyl carbons increased linearly with increasing carbon number but were, within the limits of data precision, isomer-independent for a given homolog.\(^{(157)}\)

The molecular-structure dependence of the total cross-sections for the ionization of organic compounds by electrons with energies in the region of 70 eV has been considered in terms of atomic and molecular properties. The suggestion\(^{(149)}\) that molecular cross-sections correspond to the sum of the atomic cross-sections of the molecules constituent atoms has been shown\(^{(129,150,158)}\) to be incorrect for the general case. The additivity approach has been modified to correlate total cross-sections for ionization of several classes of organic compounds by electrons having energies in the region of 70 eV,\(^{(129,152,154)}\) EI cross-sections at 70–75 eV and 11.6–11.8 eV photoionization cross-sections\(^{(159)}\) for a number of classes of organic compounds have been correlated with molecular properties such as the sum of the atomic cross-sections, polarizability, diamagnetic susceptibility and molecular volumes.\(^{(129,149,150,152,154–157,159)}\) These linear correlations are not general but are different for each class of compounds.

It is not, a priori, obvious that low-voltage cross-sections can be reliably predicted from 70–75 eV cross-sections. In this regard, the relative cross-sections for ionization of 41 low-molecular weight alkanes, alkyl chlorides, ketones, aldehydes, ethers and alcohols by 11.6–11.8 eV photons were found\(^{(159)}\) to be linearly correlated with those for ionization by 70–75-eV electrons. LVEI efficiencies have been reported for a number of relevant aromatic compounds.\(^{(160)}\) Since the ionization efficiencies were analyzed in terms of relative ionization probabilities rather then relative cross-sections, the results are considered in the next section.

### 7.7 Low-voltage Relative Mole Sensitivities for Ionization of Aromatic Compounds

Relative mole sensitivities for LVEI of aromatic hydrocarbons are tabulated in columns 6 through 11 in Table 14.\(^{(11,47,72,125–127)}\) Relative gram sensitivities were converted to relative mole sensitivities values using the
molecular masses in column 5 which were calculated from the numbers of carbons and hydrogens in columns 2 and 3, respectively. Specific Z values are listed in column 4. Conditions used in determining these sensitivities are given in the footnotes to Table 14.

The footnotes in Table 14 reveal that the relative sensitivities were not determined using a uniform set of experimental conditions. The effects of differences in experimental conditions must be considered in any evaluation of the reproducibility of relative mole sensitivities. Dempster and Nier-Johnson geometry mass spectrometers were used in a number of the sensitivity determinations. Thus, the agreement might be considered to be quite good given that the mass range in the former instrument is scanned by varying the accelerating voltage rather than the magnetic field.

The inlet and ion-source temperatures used in determining the sensitivities in set 2 were probably at least 250 °C. Ion-source temperatures for sets 1 and 5 were not reported; see footnotes a and e. Although the magnitude of the effect is dependent upon the structure of the neutral molecule, the sensitivities would reflect to some degree the use of different inlet-system/ion-source temperatures in these experiments. An increase in the contribution of hot-band transitions to the ionization efficiency caused by an increase in temperature would tend to increase the sensitivity except that sensitivities tend to decrease with increasing temperature due to increases in the thermal-energy content of the neutral which tends to increase molecular-ion fragmentations. For example, we have observed that the m/z 106 to m/z 91 signal magnitude ratio from p-xylene decreases as the inlet and ion-source temperatures are increased from 250–325 °C. The effect of different inlet and ion-source temperatures on the internal energies of the neutral prior to ionization and, hence, on sensitivities is unknown.

The footnotes in Table 14 reveal the use of different procedures for establishing the electron energies used in these sensitivity determinations. Crable et al. (11) used a nominal electron energy of 8 eV which was reported to correspond to an actual energy of 10 eV. This difference arises from contact potentials within the ion source. Thus, the actual ionizing energies used by Del Bianco et al. (72) and by Schiller (47) were undoubtedly greater than the reported nominal values of 9.2 and 10.0 eV, respectively.

(continued overleaf)
The use of fixed values of the electron energy fails to take into account the effect of field penetrations and changes in the operating conditions of the ion source on the spread of energies in the electron beam in the region of ionization. In an attempt to minimize the effect of this phenomenon, Lumpkin and Aczel,\(^{16}\) Scheppele and Sturm,\(^{126}\) and Scheppele and Miller\(^{126}\) adjusted the electron energy to maintain a fixed \(m/z 106\) to \(m/z 91\) signal magnitude ratio for \(p\)-xylene. The use of signal magnitude ratios of 100:1,\(^{126}\) 10:1\(^{126}\) and 20:1\(^{126}\) could account for some of the differences in sensitivities between sets 2, 3 and 6. It should be noted that we have routinely found that maintaining a fixed value of this ion abundance ratio requires decreases in the nominal value of the electron energy as the degree of source contamination increases for a given value of the ionizing (trap) current. This result is consistent with a broadening of the EED which in turn could result in variations in ion relative abundances and, hence, variations in relative sensitivities. The extent of acceptable ion-source contamination decreases with increasing trap current for increasing values of \(SM(106)/SM(91)\).

Deverse and King determined relative electron-impact ionization probabilities for the formation of stable molecular ions in the threshold region for a series of aromatic compounds.\(^{16}\) The dependence of the relative mole sensitivities on the magnitude of the ionizing electron energy can be quantitatively estimated using these relative ionization probabilities. It is thus unfortunate that the work of Deverse and King appears to have been overlooked to date. Using a CEC 21-103C mass spectrometer, these authors determined the parent ion ionization-efficiency curves from near the ionization thresholds to about 12 eV. Equation (57) shows that the ion signal magnitude at each value of the electron energy is the sum of the ion signal magnitudes for formation of aromatic compounds.

of various states of the molecular ion. The “tails” of the ionization efficiency curves were reported to be approximately 1.5 eV which from Figure 11 is consistent with a Maxwellian EED having a FWHM of at least 0.6 eV. At higher values of the electron energy, the ionization efficiency curves were observed to increase linearly with increasing ionization energy. The relative ionization probabilities were calculated on a mole basis from the linear portions of the molecular-ion ionization efficiency curves. The electron energy spread precluded detecting the formation of molecular ions in excited states. Consequently, the slopes effectively correspond to the sum of the ionization probabilities for formation of molecular ions in these states. Thus, from Equation (57) we obtain Equation (58) for calculating relative mole sensitivities

$$S_{\text{(mol)}} = \frac{RTP_i (V - IP_i)}{RTP_{\text{ref}} (V - IP_{\text{ref}})}$$  \hspace{1cm} (58)

where RTP$_i$ and RTP$_{\text{ref}}$ are the relative ionization probabilities for the $i$th and the reference hydrocarbons, respectively. Table 15 presents relative mole sensitivities and ionization potentials in columns 5 and 6, respectively, of Table 15.

*c* Assumed values.
Comparison of the calculated relative mole sensitivities in Table 15 with the corresponding experimental values in Table 14 reveals that the different procedures employed in establishing the electron energies used in determining these latter values could account for a significant fraction of the apparent differences between a significant number of the experimental sensitivities. Inspection of Tables 14 and 15 reveals that the experimental $S(\text{mol})_{\text{rel}}$ values for hydrocarbons in set 1 having specific $Z$ values less than or equal to $-12(\text{H})$, for benzene, chrysene and fluoranthene in set 4 and for pyrene in set 3 are exceptions that must reflect the occurrence of other phenomena.

The increase in sensitivities with increasing molecular weight is seen in Table 14 to be generally largest in set 6. However, a potentially plausible explanation for at least a portion of this result is the use of a post-acceleration detector rather than an electron multiplier as used in the other studies given the fact that the gain of electron multipliers decreases with increasing ion $m/z$ value.

The predicted $S(\text{mol})_{\text{rel}}$ values for pyrene and chrysene in Table 15 illustrate the effect of uncertainties in the ionization potentials on the magnitudes of the predicted sensitivities. As seen in column 6 of Table 15, the reported values for the ionization potentials of pyrene and chrysene range from 7.72 eV down to 7.31 eV and from 8.01 eV down to 7.72 eV, respectively. Columns 7 through 11 reveal that the lower ionization potential results in increased predicted $S(\text{mol})_{\text{rel}}$ values for pyrene with the increase decreasing from 23.0% at 9.5 eV to 10.9% at 11.5 eV. The corresponding increases for chrysene are 19.5% at 9.5 eV down to 8.3% at 11.5 eV.

The predicted sensitivities for indan and tetralin in Table 15 are seen to be significantly smaller than any of the experimental values in Table 14. Uncertainties in the ionization potentials can not account for these differences. The differences between the predicted and experimental sensitivities for these compounds is most likely to reflect phenomena such as errors in calculating the relative transition probabilities and/or greater degrees of molecular-ion fragmentation.

The $RTP$ and $IP$ values in Table 15 account for a number of anomalies that have been observed in attempts to correlate relative mole sensitivities for ionization of unalkylated aromatic hydrocarbons with quantities such as specific $Z$ values and ionization potentials quantitatively for predictive purposes. For example, the $IP$ for phenanthrene is about 0.25 eV greater than the $IP$ for anthracene. The observation of similar relative mole sensitivities for these two hydrocarbons in Tables 14 and 15 reflects the fact that the larger $RTP$ for phenanthrene essentially compensates for this difference in $IP$s. In Table 15, the predicted $S(\text{mol})_{\text{rel}}$ values for pyrene are seen to be larger or smaller than the predicted values for fluoranthene depending upon the $IP$ assumed for the former compound. The experimental values in Table 14 indicate but do not prove that pyrene has the larger relative mole sensitivity. If additional experiments either confirm this indication or determine similar $S(\text{mol})_{\text{rel}}$ values for the two hydrocarbons then the result is another example of compensating differences in $RTP$ and $IP$ values unless the $RTP$ values for either pyrene or fluoranthene or both are wrong. Although both biphenyl andacenaphthene are $-14(\text{H})$ series compounds, the experimental and predicted sensitivities for the latter are larger than those for the former. This result is consistent with the fact that the $RTP$ and $IP$ values for the acenaphthene are larger and smaller, respectively, than the corresponding values for biphenyl.

### 7.8 Summary

A number of conclusions and recommendations regarding the development of a universal database of low-voltage sensitivities are indicated by the contents of sections 7.1–7.7. The dependence of sensitivities for an agreed range of molecular structures should be ascertained and agreement should be reached regarding the acceptable range in inlet and ion source temperatures. A standard procedure for establishing the electron energy should be adopted. The simplest procedure is the attainment of a specified molecular ion to fragment ion relative abundance using a particular compound, for example, an $m/z$ (106) to $m/z$ (91) ratio of 25:1 from $p$-xylene. However, the differences in the electron energy distribution and the nominal value of the electron energy for attainment of a given relative abundance that can arise between mass spectrometers and for a given instrument as a function of the source and analyzer contamination will necessarily be reflected in the values for sensitivities to an extent presently unknown. Only rhenium filaments should be used.$(8)$ The mass dependence of detector gain should be determined for each detector system and sensitivities should be corrected for any differences in these dependencies. It would be desirable to address the consequences of differences in the mass dependence of the analyzer transmission on sensitivities albeit to do so would undoubtedly be difficult. It should be determined to what extent sensitivities such as those in sets 1–6 in Table 14, excluding those discussed above, may reasonably approximate the repeatability and reproducibility that can be realized in the determination of a universal database of low-voltage sensitivities given the experimental variables that affect these values. Finally, publications should be required to specify the basis on which either absolute or relative sensitivities were determined, for example, mole, gram or volume, and the mathematical
operations performed in converting ion abundances to sensitivities.

Common industrial analytical procedures determine the overall physical or chemical characteristics of a petroleum product, which are necessary to market the product, but these methods provide little or no information concerning specific chemical components. This article focuses on standard methods which can be used to determine the composition of individual components or classes of components within various petroleum matrices. Gas chromatography (GC) coupled with low-resolution mass spectrometry (MS) is the most useful method for quickly identifying and precisely measuring specific components or classes of components in a petroleum matrix. Direct insertion probe mass spectrometry/mass spectrometry (DIP/MS/MS) can be used for less volatile and thermally labile petroleum components.

1 INTRODUCTION

Generally accepted industrial analytical procedures utilized for commercial petroleum products rarely determine any of the numerous actual chemical components in those products. Most industrial procedures only define the overall physical or chemical characteristics of a petroleum product that are necessary to market the product. Physical properties such as boiling range, density, viscosity, flash point, and vapor pressures are measured. Specific chemical characteristics such as carbon, hydrogen, and nitrogen content, total sulfur, average molecular weight, octane number, or cetane number are determined. This article will focus on the composition of individual components or specific classes of components in the common commercially available refined or natural petroleum products. Specific components or classes of components can be identified quickly and precisely quantitated using GC coupled with low-resolution MS, i.e. gas chromatography/mass spectrometry (GC/MS). DIP/MS/MS can sometimes be used for less volatile and thermally labile petroleum components. DIP/MS/MS is also a useful technique for determining the elemental sulfur content of crude oils. The selection of appropriate internal surrogates will greatly enhance identification, precision, and accuracy.
2 GENERAL COMPOSITION OF COMMERCIAL PETROLEUM PRODUCTS

Petroleum products are extremely complex. Crude oils contain thousands of hydrocarbon components, many of which have not been fully characterized. Some components are unique to only a few specific crude sources. A second complication is the large and varying range of concentrations of possible components. Individual component concentrations will range from parts per billion to percentage levels. This range will far exceed the dynamic limits of most analytical instruments. A third complication is that many components are extremely similar. Although hundreds of these components are structurally unique, still thousands of other components are isomeric. Many of these isomeric petroleum hydrocarbons have very similar chemical and physical properties.

It will be useful to describe the major types of components in common commercial liquid petroleum products. These products are listed below in ascending boiling ranges.

- **Aviation gasoline** contains primarily alkylate, which is a highly branched saturated hydrocarbon mixture ranging from hexanes to nonanes, plus tetraethyllead. It does not contain aromatics or olefinic (unsaturated) hydrocarbons. It has a nominal boiling range of 30–220 °C.

- **Motor gasoline** contains straight run gasoline, which includes all of the natural crude oil components in the gasoline boiling range. Additionally, gasoline contains special refinery streams such as alkylate, reformate (which is mainly toluene), ethylbenzene, xylenes, and C5-benzenes, some benzene and naphthalenes, plus trace amounts of heavy polycyclic aromatic hydrocarbons (PAHs), olefinic alkylate, and sometimes substantial levels of methyl tert-butyl ether (MTBE) or other oxygenates. The nominal boiling range of gasoline is 30–220 °C.

- **Kerosene** has a very significant normal paraffin content ranging from nonane to nonadecane, usually with a maximum near tridecane or tetradecane. Kerosene also contains lower levels of aromatics and some naphthenics (cyclic aliphatics) in the corresponding boiling range. Kerosene does not contain olefinic hydrocarbons. Its nominal boiling range of major components is 140–240 °C.

- **Aviation jet fuel** has a composition and boiling range similar to those of kerosene.

- **Diesel fuel** also has significant normal paraffin content, which ranges from decane to tetracosane, and usually has a maximum near hexadecane. Diesel also contains some aromatics and naphthenics with corresponding paraffinic boiling range. Diesel usually contains ethylhexyl nitrate as a cetane enhancer. Diesel does not contain olefinic hydrocarbons. Its nominal boiling range is 220–340 °C.

- **Home heating fuel** has a composition and boiling range similar to diesel, but does not contain ethylhexyl nitrate.

- **Motor oils** primarily contain octadecane to C32 paraffinic, naphthenic, and aromatic hydrocarbons along with various lubricant additives. Motor oils do not contain olefinic hydrocarbons. Modern fresh motor oils do not contain nonalkylated PAHs. Many motor oils contain low levels of distinctive biomarkers. Motor oils may contain or be completely composed of synthetic esters or polyolefins. These synthetic motor oils can be easily differentiated from natural motor oils. The boiling point of motor oils starts around 330 °C and will extend beyond 400 °C.

Within the above refined petroleum product classifications, the general chemical composition is fairly similar. However, the relative distributions of these chemical components are unique and can generally be useful for distinguishing one fuel from another in the same class.

- **Crude oils**, in contrast to refined products, vary greatly from each other. Still, a few generalities can be made. Crude oils usually contain a distinctive normal paraffin content over a wide boiling range. Crude oils do not contain olefinic hydrocarbons. They have relatively fewer branched-chain alkanes and more cycloparaffins in the gasoline range than motor gasoline. Crude oil will contain low levels of distinctive biomarkers, which are particularly useful fingerprints for identifying a particular crude oil. They generally contain low levels of nonalkylated PAHs. Crude oils may also contain elemental sulfur, S8.
aliphatics rapidly from aromatics. Automated high-performance liquid chromatography (HPLC), if available, can also be very useful. Typically, crude oils, gasolines, diesel fuels, and many motor oils contain 15–30% aromatics. Boiling fractions will again simplify the petroleum matrix. Gasoline, kerosene, diesel fuel, and lubricants are, to a first approximation, boiling range fractions of crude oil. GC using nonpolar columns is a quick procedure to separate hydrocarbons by boiling point.

3.2 Gas Chromatography Combined with Low-resolution Electron Ionization Mass Spectrometry

Only GC/MS can resolve and identify petroleum products at the molecular level. The gas chromatograph has the separating power to resolve the thousands of compounds in petroleum products. The mass spectrometer will further separate even unresolved chromatographic peaks based upon their mass spectral characteristics. The mass spectrometer has a sufficient dynamic range and sensitivity to measure both the major and trace components. Most important, the mass spectrometer has the specificity to identify or at least characterize most of these complex hydrocarbons.

3.2.1 Instrumental Conditions for Gas Chromatography/Mass Spectrometry

Most product samples can be separated at least partially by medium-resolution GC using splitless injection on to a nonpolar capillary column (30 m × 0.25 mm ID or 20 m × 0.18 mm ID columns, 100% methylsilicone or 95% methyl–5% phenylsilicone phase). Complex samples require high-resolution GC conditions, using 100 m × 0.25 mm ID or 40 m × 0.10 mm ID capillary columns. The narrow-bore columns are preferable owing to the fast analysis time and low column bleed into the mass spectrometer detector, although some commercial gas chromatographs cannot handle the high head pressure required. The mobile phase velocity is set to 30 cm s⁻¹ for helium carrier gas. A slow oven ramp is used to provide maximum chromatographic separation, up to the upper temperature limit of the column (usually 350–400 °C).

The mass spectrometer detector is configured with a direct capillary interface. It is operated in an electron ionization (EI) mode using an ionization energy between 50 and 100 eV. The mass range is set in full scan mode to 29–500 Da at unit resolution. The scan time is set to achieve at least eight scans per GC peak width at half-height. Quantitation is achieved using the most unique mass for each target component, usually the molecular ion, which is measured against the closest eluting internal standard of similar polarity. Isotopic internal surrogates will greatly enhance identification, precision, and accuracy.

3.3 Direct Insertion Probe Mass Spectrometry/Mass Spectrometry

When a petroleum component is not volatile and/or thermally labile, GC will be ineffective. However, DIP/MS/MS can often be an effective substitute for selected compounds. The first of the tandem mass spectrometers replaces the gas chromatograph. It is used to select a characteristic set of masses for a targeted compound, usually its molecular mass. The second mass analyzer is used to discriminate between those compounds with similar masses. An internal surrogate is still required for precision and accuracy. This technique is rapid and requires minimum sample preparation. The high selectivity can be tailored to the analyte even in the most complex of matrices, such as crude oils. DIP/MS/MS can be used to measure elemental sulfur, S₈, in crude oils. This is an excellent example of achieving selectively, high sensitivity, and accuracy with minimal analysis time.

3.3.1 Instrumental Conditions for Direct Insertion Probe Mass Spectrometry/Mass Spectrometry

The surrogate of the compound of interest is spiked at a known concentration into the petroleum sample. The spiked sample is then placed on a direct thermal probe and is slowly sublimed at low temperature directly into the source of the mass spectrometer. Although this slow evaporation or sublimation does provide some separation, the traditional total ion mass scan would still display only a continuous spectrum with hits at virtually every mass. However, when the tandem mass spectrometer is sequentially programmed to scan selective daughter ions that are key masses for the target compound and alternately for the surrogate compound, then quantitation can be achieved.

The mass spectrometry/mass spectrometry (MS/MS) conditions should be optimized for the target analyte. The selected ionization energy should maximize the target component’s parent ion. Generally, the molecular ion is selected, but other distinctive ions may be used as the parent ion. The collision offset energy that provides the daughter ion fragments should also be optimized.

3.4 Specialized Internal Petroleum Surrogates

The surrogate compounds should have the same physical and chemical properties as the analyte and should not be naturally present in the petroleum matrix. Isotopically labeled aliphatics and aromatics make ideal surrogates. Isotopic surrogates over the entire petroleum hydrocarbon boiling range are generally available commercially. These surrogates are simple to use and easy to calibrate against target analytes. They both make identifications easier and greatly enhance accuracy of measurements.
Deuterated surrogates should be prepared and added just prior to analysis due to the possibility of isotopic exchange with solvents at high or low pH levels. Carbon-13 surrogates are stable, but are much more expensive. Examples of the various commercially available hydrocarbon surrogates and the corresponding petroleum product are as follows:

- Gasoline-range surrogates – percentage range concentrations of octane-\(d_{18}\), benzene-\(d_6\), toluene-\(d_8\), ethylbenzene-\(d_{10}\), styrene-\(d_8\), butylbenzene-\(d_{12}\), 4-ethyltoluene-\(d_5\), and naphthalene-\(d_8\); parts per million range deuterated PAHs.
- Kerosene- and diesel-range surrogates – parts per thousand range concentrations of hexadecane-\(d_{34}\), methyl-naphthalene-\(d_{10}\), butylbenzene-\(d_{14}\); parts per million range deuterated PAHs.
- Motor oil-range surrogates – parts per thousand range concentrations of octacosane-\(d_{58}\), nonylpyrène-\(d_{58}\), butylbenzene-\(d_{14}\); parts per million range deuterated PAHs.
- Heavy crude oil-range hydrocarbons – same as motor oil. Use \(^{34}\)S8 to determine elemental sulfur.
- Isotopic derivatives of common fuel additives such as deuterated MTBE, methyl-\(d_{12}\) tert-butyl ether.

4 APPLICATIONS

4.1 General Strategies for the Mass Spectrometry Analyses of Petroleum Components

Application examples of four general strategies for analyzing components in liquid petroleum matrices will be described. Very similar approaches can be applied for the analysis of just about any individual or group of semivolatile components found in any petroleum product. These general mass spectrometric strategies can be summarized as follows:

- The analysis of known, well-characterized and stable components that are present at moderate concentration levels (approximately 50 ppm or greater). The GC/MS analysis of the specific aromatics and oxygenates in gasoline will be used to illustrate this approach.
- The analysis of known, well-characterized and stable components that are present at low concentration levels (approximately 10 ppm or less). The HPLC cleanup and subsequent GC/MS analysis of the 2-aminonaphthalene in motor oil will be used to illustrate this approach.
- The analysis of less defined components that are present at moderate concentration levels (about 50 ppm or greater). Two approaches will be used as examples. First is the GC/MS analysis of specific alkylated PAHs in crude oil. The comparative analysis of trimethylphenanthrene and trimethylbenzothiophene will be used to illustrate this approach. Second is the DIP/MS/MS analysis of the specific higher molecular weight alkylated PAHs in crude oil. The analysis of alkylbenzothiophenes and alkylbenzo-thiophene in heavy oil fractions will be used to illustrate this approach.

4.2 General Strategy for Well-characterized Components at Moderate Concentrations: Analysis of the Individual Aromatic Components in Gasoline

The GC/MS analysis of the specific aromatics and oxygenates in gasoline will be used as an example of the general strategy for the compositional analysis of known components at moderate concentrations. The gasoline matrix is the simplest of the liquid petroleum products, yet it still presents a challenge to analysis. Various GC methods have been used for many years to identify and quantitate gasoline components, but these methods have significant problems. Even when very high-resolution GC methods are used, co-eluting peaks and multiple isomers with different retention times complicate the resulting chromatograms. A stand-alone MS method, American Society for Testing and Materials (ASTM) Method D2789, which does not use a prior chromatographic separation, also has been used to determine the aromatic concentration in gasoline.\(^{(1)}\) However, ASTM Method D2789 only provides general gasoline component classifications (i.e. paraffins, monocycloparaffins, dicycloparrfans, alkylbenzenes, indans plus tetralins, and naphthalenes). Furthermore, ASTM Method D2789 lacks precision because it assumes the probable distribution of aromatics in gasoline and requires that the gasoline be relatively free of olefins.

A combination of GC and MS overcomes the lack of analytical target specificity that is characteristic of the individual techniques when those techniques are used independently. GC/MS is an orthogonal hyphenated method that combines multiple complementary separation capacities of both methods. This combination results in an extremely powerful technique for the analysis of gasoline. The general strategy for applying GC/MS to the component analysis of aromatics in gasoline will now be described. A very similar approach can be applied
for the analysis of just about any individual or group of semivolatile components found in any petroleum product.

4.2.1 Gas Chromatography/Mass Spectrometry of Aromatics in Gasoline Using American Society for Testing and Materials Method D5769

The United States Environmental Protection Agency (USEPA), specified in the Federal Register in 1994 that GC/MS must be used to determine the total aromatics in gasoline. The USEPA established performance guidelines, but only very general procedural guidelines. It permits the use of any GC/MS conditions and internal standards as long as the results are within a relative error of 2.0%. This progressive legislation allowed the petroleum and environment laboratories to develop their own particular methodologies. The Texaco Upstream Technology laboratory worked closely in a joint effort with other laboratories to develop specific details to optimize the performance and minimize the complexity of this new USEPA method. The result of this effort was ASTM Method D5769.

The GC/MS conditions for ASTM Method D5769 are summarized as follows. The gas chromatograph is equipped with a 100% polymethylsiloxane open-tubular GC capillary column. The method suggests using a 60 m x 0.32 mm ID column which is operated at 50°C (1 min), ramped at 2°C min⁻¹ to 190°C. The total acquisition time will be 71 min. The mass spectrometer is operated under 70 eV EI conditions. The method required a minimum full-scan sampling rate of five scans across peak widths at half-height.

The ASTM Method D5769 internal standards are perdeutero benzene, perdeuteroethyl benzene and perdeuteronaphthalene. Perdeuterotoluene is optional. (The hydrogen atoms in a perdeutero compound have been totally substituted for deuterium atoms.) The resulting compound is an internal surrogate with almost the same GC retention time as the corresponding aromatic component. The deuterated surrogates will actually have a slightly lower GC retention time. Of course, the mass spectrum of the deuterated surrogate will be completely different, since deuterium has an atomic mass of 2 Da. However, the deuterated surrogate will have an analogous mass spectrum corresponding to the natural component spectrum. The relative GC/MS response factors for individual pure components (from benzene through all of the major aromatics up to C₁₁) are measured relative to the response of the deuterated standards.

A typical calibration, in this case for benzene, is shown in Figure 1. The coordinates are relative response vs relative amount. The slope of the line is the response factor. In our laboratory each of five concentrations across the calibration range was measured at least three times prior to calculating response factors. The fit is essentially linear with a coefficient of correlation of 0.9999. All major aromatic compounds are calibrated separately, generally using molecular ions in the mass spectrum for quantitation for most species.

The deuterated internal standard mix is weighed into a 10-g sample of gasoline to the nearest 100 µg. A 12-component quality control (QC) mix is prepared by weight. The QC sample is then run. ASTM Method D5769 specifies that each individual aromatic species in the QC mix must be measured within 5% relative of the true, weighed concentration. Any additional unspecified experimental conditions used are acceptable, as long as this specification is obtained. The weight percentage of each target aromatic component is then calculated. (The volume percentage of that component is calculated from the density of the pure component relative to the sample density.) A synthetic gasoline consisting of known weighed amounts of pure gasoline components is then run as a QC sample. The measured total aromatics for this QC standard must be within 2.0 wt% of the weighed total aromatics. The ASTM Method D5769 statistical specifications are significantly tighter than those specified by the USEPA, since the USEPA requires that only the total aromatics of the QC mix be within 2% accuracy.

This laboratory developed a very rapid and more precise modification for ASTM Method D5769. The analysis

![Figure 1 Calibration curve for benzene. The slope is a straight line, which is indicative of a linear response factor.](image-url)
time was greatly reduced by applying fast GC column technology. Our laboratory specifies using either a 20 m × 0.10 mm ID or 20 m × 0.18 mm ID 100% poly-methylsiloxane open-tubular column with a 25 °C min⁻¹ ramp rate. These GC conditions reduce the total acquisition time to only 9 min vs 71 min and the chromatography is still well within the chromatographic resolutions specified in ASTM Method D5769. These narrow-bore columns are available from numerous manufacturers. Figure 2 shows a selected ion chromatogram in the range of C₉ alkylbenzenes (trimethylbenzenes, ethylmethylbenzenes, and propylbenzenes). The C₉ benzenes eluted totally within 6 min and with a GC resolution which meets or exceeds that published in ASTM Method D5769 for a 90-min version using the more traditional wider bore and longer columns. The peak widths are approximately 0.5 s. For such a peak width, ASTM Method D5769 requires a full-scan MS sampling rate of 10 scans s⁻¹ (five scans across the peak at half-height). The MS sampling rate was actually 13 scans s⁻¹ in this case. Most commercial mass spectrometers can easily scan at these rates.

4.2.3 Other American Society for Testing and Materials Method D5769 Modifications

The modified method improves the precision of ASTM Method D5769 while staying within its method parameters. The additional precision was achieved through the following three modifications. First, the addition of perdeuterotoluene to the internal standard mix increases the precision of toluene determination significantly. Perdeuterotoluene is optional for the standard version and has the least precision of any component in the standard ASTM Method D5769. The modified internal standard mix is added at approximately 10% by weight to each sample to give approximately 1 wt% benzene-d₆, 7 wt% toluene-d₈, 1 wt% ethylbenzene-d₁₀, and 1 wt% naphthalene-d₈. The result significantly increases the precision, since toluene generally has one of the highest concentrations of any individual component in gasoline. When toluene is quantitated against perdeuterobenzene, generally a quadratic calibration fit is required. However, when perdeuterotoluene is added at 7% in the sample, the linear range of the calibration curve is extended by almost one order of magnitude. Figure 3 shows linear calibration curves for toluene with an excellent correlation coefficient.

Second, the effective instrumental operational dynamic range of the mass spectrometer is significantly enhanced using microbore GC columns. The sensitivity specification in ASTM Method D5769 requires a detection limit of diethylbenzene at 20 ppm and a calibration curve for toluene that extends to 20%. Significant care must be taken in tuning the mass spectrometer to achieve such a wide dynamic range, but the selection of the proper GC conditions can extend the dynamic range of the GC/MS instrument far beyond the range of the MS detector alone. By using narrow-bore GC columns (0.1–0.18 mm ID) with a fast GC temperature ramp, it is possible to sharpen the small peaks while broadening the large peaks (column saturation), thus limiting the amount of material passing into the ion source at any given time. Although major components, such as toluene, may be saturated in the GC column, the MS detector is not saturated. The precision of the analysis is not affected and even the chromatographic resolution is still acceptable.

Third, the internal standard calculation requirements of ASTM D5769-95 can be another source of error. The method suggests using molecular ions for calibration,

</table>

but many deuterated standards are only commercially available at less than 100% nominal isotopic purity. For example, perdeuteroethylbenzene is available in nominal 98% isotopic purity. Therefore, a problem may occur when this imperfect internal standard is used. The molecular ion (unfragmented ion) will be distributed between \( m/z 116 \) (\( C_8D_{10} \)) and \( m/z 115 \) (\( C_8D_9H \)). Since \( m/z 116 \) cannot lose hydrogen, \( m/z 115 \) cannot be a fragment of \( m/z 116 \). A batch of perdeuteroethylbenzene internal standard deuterated to 98.1% has an \( m/z 115/116 \) ratio of 20%, whereas another batch deuterated to 99% has an \( m/z 115/116 \) ratio of 10%. Using just the \( m/z 116 \) ion to quantitate this internal standard, as the method suggests, could cause significant error since the internal standard added to samples could be from a different batch than that used for calibration. In our laboratory, the sum of the intensities observed for both the molecular ions of the zero hydrogen and one hydrogen analogs of each internal standard were used to maximize precision and accuracy. For example, \( m/z 99 \) and 100 were used for toluene-\( d_8 \), as seen in Figure 3.

Table 1 shows for a typical sample the precision that can be obtained when incorporating these three easy to implement modifications. Total aromatics of the six repetitive analyses range within 0.48% of each other and within a comfortable 0.30% of the mean. The EPA requires that the calibration mixture, which is less complex to analyze than actual gasoline, to agree within 2.0% of the actual measured preparation value.

4.2.4 American Society for Testing and Materials Method D5769 Bias

ASTM Method D5769 contains some bias. The USEPA mandate does not include the higher aromatics such as \( C_{10} \) alkynaphthalenes, \( C_{12} \) alkylbenzenes, styrenes, and alkylindenes, which are found in gasoline, but at relatively low concentrations. ASTM Method D5769 tries to correct this problem by selecting pentamethylbenzene to establish the response factors for the uncalibrated heavier alkylbenzenes. Unfortunately, out of the hundreds of \( C_{11} \) and \( C_{12} \) alkylbenzenes, only pentamethylbenzene and hexamethylbenzene do not contain benzylic carbon–carbon bonds. Alkylbenzenes with a weak benzylic \( C\)–\(N\) bond have molecular ions that are approximately 30% smaller than those for alkylbenzenes without a benzylic \( C\)–\(C\) bond. Therefore, estimating these uncalibrated components against the pentamethylbenzene calibration curve will produce results which are 30% lower than the actual value. In our laboratory, uncalibrated components are quantitated using response factors calculated from the aggregate response of the calibrated compounds butylbenzene, 1,4-diethylbenzene, and 1,2-diethylbenzene. These components are reported as ‘long chain \( C_4 \)-benzenes’. When a long-chain alkylbenzene is
PETROLEUM AND LIQUID FOSSIL FUELS ANALYSIS

used to estimate for uncalibrated compound response, the bias will disappear.

4.2.5 Expanding the Scope of American Society for Testing and Materials Method D5769

Again the method for total aromatics in gasoline can serve as a template for the analysis of any component in gasoline. Additional gasoline components can be added to the list of eluting targets with essentially no additional analysis time or loss in quantitative quality. For example, this laboratory easily modified ASTM Method D5769 to include MTBE and TAME. MTBE and TAME are common oxygenate additives that can be found in gasolines, especially during winter months. The fragment ion at \( m/z \) 73 was used to measure the two ethers, since the molecular ions of these nonaromatic species are weak or absent in their EI spectra. ASTM Method D5599 is a GC method with oxygen flame ionization detection (OFID) that is recommended for measuring gasoline oxygenates. Both methods produce essentially the same answer, but the modified ASTM Method D5769 also simultaneously provides gasoline aromatic content. Figure 4 is a plot of the results for both methods at low and high concentration levels of MTBE and TAME. The response curve is linear throughout the range.

4.3 General Strategy for Well-characterized Components at Low Concentrations: Analysis of the Trace Components in Refined Oils and Crude Oils by Gas Chromatography/Mass Spectrometry and Liquid Chromatography

The analysis of trace-level components in motor oil or heavy crude oils is one of the most challenging petroleum analyses. Heavy hydrocarbon mixtures are more difficult to analyze because the individual components have higher molecular weights. Large molecules contain more possible combinations of atoms. There is a continuous array of molecules with similar boiling points and molecular weights throughout even narrow boiling distributions. When GC/MS alone is applied for the analysis of trace components in a heavy petroleum matrix, the analyte ions can be lost in a continuum of interfering background noise. In these cases, solid-phase chromatography or HPLC can often be used to reduce the complexity of the matrix. The analysis for 2-aminonaphthalene in motor oil using HPLC cleanup prior to GC/MS will be used as an example.

4.3.1 Analysis for 2-Aminonaphthalene in Motor Oil Using High-performance Liquid Chromatography Clean-up Prior to Gas Chromatography/Mass Spectrometry

2-Aminonaphthalene has long been recognized as a human carcinogen. It is crucial to establish that it is not present even at trace levels in petroleum products which may come into contact with potable water or food packaging equipment. The motor oil is spiked at the low parts per million levels with a deuterated surrogate of 2-aminonaphthalene and analyzed by a general strategy similar to the general methodology used for determining the aromatic content of gasoline. The gas chromatograph was operated with column

![Figure 4](image1)

**Figure 4** ASTM Method D5769, when modified to include oxygenates, produces the same results as ASTM Method D5599. MTBE and tert-amyl methyl ether (TAME) (\( m/z \) 73) calibrated against benzene-\( d_6 \) (\( m/z \) 84).

![Figure 5](image2)

**Figure 5** Selected ion traces at (a) \( m/z \) 143 and (b) \( m/z \) 150 for an oil sample spiked at 5 ppm with 1-aminonaphthalene and 2-aminonaphthalene-\( d_7 \) prior to HPLC cleanup. The chromatogram fails to indicate their presence above the background noise.
temperature programming from 70°C at 8°C min⁻¹ to 320°C. A 1-µL volume of sample was injected on to a 30 m × 0.25 mm ID, 0.25-µm phase thickness, fused-silica capillary 5% phenyl–methylsilica column with a flow rate of 40 cm s⁻¹. The mass spectrometer was operated at nominal mass using EI with an ionization energy of 70 eV. The instrument was scanned over a mass range from 50 to 250 Da every 0.75 s. The analysis failed. There are too many interfering components in the same retention time window and with the same fragment ions. Figure 5(a) and (b) shows GC/MS selected ion chromatograms of motor oil spiked at the 5 ppm level with both 1-aminonaphthalene and 2-aminonaphthalene-d₂. Both compounds will elute between 20 and 21 min under these GC conditions. The molecular ion trace for aminonaphthalenes, m/z 143, is questionable. The molecular ion trace for the deuterated surrogate, m/z 150, shows only noise. Even though the results are ambiguous, they are superior to others. One State and two commercial environmental laboratories that initially used straight GC/MS without HPLC cleanup and had initially reported 2-aminonaphthalene to be present in this oil at the low parts per million level. The commercial laboratory then also verified that 2-aminonaphthalene was absent.

This laboratory developed an HPLC procedure that will quickly and unambiguously determine if 2-aminonaphthalene is not present in refined oils or crude oils at trace levels. First, 25 µL of the original spiked oil was injected on to a 250 × 4.6 mm ID cyano column and eluted with a 5% solution of methylene chloride in hexane, then the fraction containing the aminonaphthalenes was collected and evaporated to about 25 µL. Finally, the GC/MS procedure was repeated under the previous conditions. Figure 6(a) and (b) shows selected ion chromatograms of the cleaned-up oil. The deuterated 2-aminonaphthalene surrogate and 1-aminonaphthalene are clearly present at the 5 ppm level. There is no evidence of the natural 2-aminonaphthalene, since that compound would have eluted just after its deuterated surrogate when using these GC conditions. The retention time for the natural (non-deuterated) 2-aminonaphthalene was verified in subsequent analyses.

This procedure has a lower limit of detection of approximately 500 ppb. Still lower detection limits would have been achieved with selected ion detection. However, the mass spectrometer was operated using a full mass range in this case to assure that the HPLC cleanup procedure completely eliminated hydrocarbon interferences from the oil. This procedure was then supplied to the commercial environmental laboratories that initially used straight GC/MS without HPLC cleanup and had initially reported 2-aminonaphthalene to be present in this oil at the low parts per million level. The commercial laboratory then also verified that 2-aminonaphthalene was absent.

Special precautions must be taken when using a deuterated surrogate, since deuterium can exchange with some solvents and matrices, especially under acidic or basic conditions. In one case, one of the labeled aromatic ring positions adjacent to the amino group exchanged with the solvent, methylene chloride, during prolonged storage. A 6-week-old methylene chloride solution showed over 80% 2-aminonaphthalene-d₆ and only 3% of the original 2-aminonaphthalene-d₇. Standards should be prepared shortly before use and stored, if necessary, cold.

### 4.4 General Strategy for the Analysis of Less Defined Components Present at Moderate Concentrations

The most challenging target analyte is a target that is poorly characterized. Many petroleum components have not yet been isolated and therefore their actual physical properties are unknown. Furthermore, many components may never be isolated because of the complexity of the petroleum matrix and the expense of thorough analyses. In these cases, it is more practical to analyze classes of hydrocarbons, which can be loosely defined by their basic chemical properties and carbon framework. Members of individual class types will consist of isomers and homologs, varying from each other only by position and type of aliphatic groups attached to the particular carbon framework. These carbon frameworks can be generalized as various combinations of aliphatics, olefinics, naphthenics, aromatics, and naphthoaromatics. Traditional methods were developed in the 1950s using batch-inlet electron ionization mass spectrometry (EI/MS). These hydrocarbon type analyses are still useful in some cases for

![Figure 6](image-url)

**Figure 6** Selected ion traces at (a) m/z 143 and (b) m/z 150 for an oil sample spiked at 5 ppm with 1-aminonaphthalene and 2-aminonaphthalene-d₂ after HPLC cleanup. The chromatogram clearly indicates their presence of both compounds.
4.4.1 Gas Chromatography/Mass Spectrometry Analysis of Alkylated Polycyclic Aromatic Hydrocarbons in Petroleum Products

GC/MS response factors for alkylated polyaromatic hydrocarbons are either difficult to generate or unavailable. However, the GC data are internally consistent over short boiling ranges, when comparing within one or within two similar homologous series. For instance, the relative amounts of two different alkylated PAH homologs, which are both alkylated to the same extent, are commonly used to differentiate middle distillate products or crude oils from each other. For example, Figure 7 shows the total ion chromatogram of a diesel fuel and two selective ion traces extracted from it. The selective traces show only trimethylphenanthrenes ($m/z$ 220) and trimethyldibenzothiophenes ($m/z$ 226), which eluted in the 20–22 min time interval. The total peak areas of trimethyldibenzothiophenes are then divided by the corresponding sum of the trimethylphenanthrenes. This ratio is called the D3/P3 index and is characteristic of the particular sample. For example, the D3/P3 index of a low-sulfur diesel fuel will range typically from 0.10 to 0.30. An Arabian Light Crude Oil may have an index as high as 4.06. The general pattern within a particular alkyl-PAH sequence is also

Figure 7 Total ion chromatogram of a diesel fuel with selected ion traces at $m/z$ 220 and 226, eluting in the 20–22 min time interval.

characterizing middle distillates and vacuum gas oils. However, GC/MS and DIP/MS/MS now permit these traditional analyses to be customized more selectively within individual hydrocarbon types. The information is especially useful for predicting general physical and chemical properties of petroleum products.

Figure 8 Total-ion, low-voltage EI mass spectrum of a heavy petroleum fraction.
valuable for determining the source or fingerprints for a petroleum product.

4.4.2 Direct Insertion Probe Mass Spectrometry/Mass Spectrometry Analysis of the Specific Alkylated Polycyclic Aromatic Hydrocarbons in Crude Oil

The heavier components of crude cannot be analyzed by GC/MS since they cannot be effectively resolved by GC or are simply not volatile. However, DIP/MS/MS is useful for analyzing specific higher molecular weight alkylated PAHs in crude oil. The general procedure follows: the high-boiling crude oil cut is placed in a quartz direct insertion probe tube and inserted into the source of a mass spectrometer. The sample is heated from 50 to 450 °C at 50 °C/min \(^{-1}\) and held for 5 min. The mass spectrometer is operated under EI conditions using an ionization energy of 20 eV. The resulting total ion mass, presented in Figure 8, is of low value. It does clearly show a bimodal ion distribution. The lower mass distribution represents fragmentation ions and the higher mass distribution represents a continuum of molecular ions. However, this molecular ion distribution can be nearly resolved using parent mode MS/MS. The parent ions of \(m/z\) 197, 213, 215, 217, 221, 219, 223, and 225 were sequentially scanned. Figure 9 reveals a distribution of dibenzothiophenes that are generated by the parent ions of \(m/z\) 197. Figure 10 reveals a distribution of benzothiophenes that are generated by the parent ions of \(m/z\) 217.

4.5 General Strategy for Well-characterized but Thermally Labile Components at Moderate Concentrations: Direct Insertion Probe Mass Spectrometry/Mass Spectrometry for the Determination of Elemental Sulfur in Crude Oil

Elemental sulfur in crude oil can range from trace amounts to low percentage levels in mixtures, which are sometimes nonhomogeneous. The traditional analyses for measuring sulfur in crude oil have been limited to wet chemical methods. These techniques are time-consuming, are cumbersome, require skilled technicians, and still generally lack accuracy and precision. These analyses are further complicated because of the physical and chemical properties of elemental sulfur (sulfur has a low sublimation temperature, low and differing solubilities in the various crude oils, moderate reactivity with air, and even a modest thermal reactivity with hydrocarbons in the crude oil matrix).

DIP/MS/MS, when used in conjunction with an isotopically labeled sulfur-34 surrogate, provides a rapid and accurate method for determination of natural sulfur in crude oils.\(^{10}\) Elemental sulfur-34 is spiked directly into the crude oil at 0.1 wt% and allowed to dissolve thoroughly overnight. The homogeneous spiked sample is then placed on a direct insertion probe and introduced into the mass spectrometer while being held at 30 °C. The sulfur is non-reactive at this low temperature, but will still sublime easily in the low-pressure environment of the mass spectrometer’s ion source. Since the probe was never heated, most of the crude remains on the probe.

![Figure 9](image_url) Mass spectrum showing parent ions of \(m/z\) 197.
Figure 10 Mass spectrum showing parent ions of m/z 217.

Figure 11 Normal total-ion EI mass spectrum of a direct insertion probe crude oil sample. Sulfur peaks are not prominent.

The mass spectrometer was sequentially programmed for one full-range scan and four daughter mode scans under EI conditions at 70 eV ionization energy. The full-range scan was from 250 to 285 Da. The daughter ions of m/z 256, 258, 270, and 272 were collected starting at mass 75 to the mass of the daughter ion minus 2 Da. The collision offset was set at 10 eV. Scan time was 1 s for each scan. Figure 11 shows the full-range mass scan. The key molecular ions for elemental sulfur at 256 Da and the surrogate at 272 Da are completely obscured by a continuum of interfering hydrocarbon ions. No successful quantitation could be obtained from the straight full-scan mass spectrum. Figure 12(a) and (b) presents the daughter ion scans of m/z 256 and 272. The parent ion of m/z 256 (32S8) produces a strong daughter ion at m/z 160 (32S5), representing the loss of three atoms of sulfur-32. The parent ion of m/z 272 (34S8) produces a strong daughter ion at m/z 170 (34S5), representing the loss of three atoms of sulfur-34. The experimentally measured data for the daughter ions of m/z 160 and 170 are then normalized for the initial relative abundances of the parent ions of m/z 256 and 272 in the pure molecular clusters of the natural sulfur and the enriched sulfur. For example, the abundance of 32S8 in natural elemental sulfur is 66.5%. Dividing by 0.665 normalizes the experimental measurements. The molecular isotopic abundances for the natural sulfur and the surrogate abundance were easily determined from the mass spectra of the pure components. Figure 13(a) and (b) shows the molecular ion distribution and relative contributions for the parent ions. Equation (1) can be used to calculate weight percentage of sulfur in the oil:

\[
sulfur (\text{wt\%}) = \frac{\text{normalized response of natural sulfur}}{\text{normalized response of } ^{34}\text{S}}.
\]  

(1)

Two precautions should be considered. First, when working with isotopic internal standards, general response factors will take into account variations of the nominal values in isotopic distributions stated by the supplier. However, when a new batch of standards is
used, new response factors must be generated. Second, elemental sulfur is hygroscopic and the extent of hydrate formation must be determined in the surrogate so that the true amount of spike will be known.

5 CONCLUSION

Specific hydrocarbon components or classes of components can be quickly identified and precisely quantitated using GC coupled with low-resolution MS. DIP/MS/MS can sometimes be used for less volatile and thermally labile petroleum components. The selection of appropriate internal surrogates will greatly enhance identification, precision, and accuracy. The application of four general strategies for analyzing components in liquid petroleum matrices serves as templates only. Very similar approaches can be applied for the analysis of just about any individual or group of semivolatile components found in any petroleum product.

1 INTRODUCTION

Crude oils exhibit a broad range of elemental composition because they are formed by a combination of deposition, degradation, and transformation of ancient organics from different biosources.\(^1\) In addition to hydrocarbons, crude oil contains a multitude of minor impurities, including sulfur-, nitrogen-, and oxygen-bearing heterocyclics, soluble nickel and vanadium compounds and a variety of trace metals that are removed in refining. When crude oil is distilled, a residual fraction containing molecules that do not volatilize is drawn off the bottom. This “resid” has an increased concentration of the heterocyclics and practically all of the metals. However, resid is valuable because it compares favorably with alternate hydrocarbon resources (bitumen, heavy oil, shale oil, and coal liquids) in terms of these deleterious contaminants and it is accessible in the refinery.\(^3\)\(^,\)\(^4\) This article introduces the common techniques available for analysis of sulfur, nitrogen, nickel, vanadium, and trace metals in this challenging organic matrix.

2 PETROLEUM RESIDS

2.1 Origin

Commercially, resids are produced in the distillation unit that is the initial refinery treatment of a crude oil. In this unit, the oil continuously flows in sequence through a desalter, heat exchangers, an atmospheric pipestill (APS) and a vacuum pipestill (VPS). The bottoms from the APS (650 °F (343 °C) or atmospheric resid) are reheated and distilled under vacuum (15–100 Torr) in the VPS. In this scheme, both distillation units keep the actual temperature below 650 °F (343 °C) to minimize cracking of the oil.

In addition to the continuous distillation in a refinery, laboratories use batch distillation methods to produce experimental “resids” with different distillation bottoms (vacuum resid) with an atmospheric equivalent boiling point (AEBP) of 1050 °F (566 °C).\(^3\)\(^,\)\(^4\) In this scheme, both distillation units keep the actual temperature below 650 °F (343 °C) to minimize cracking of the oil.

In addition to the continuous distillation in a refinery, laboratories use batch distillation methods to produce experimental “resids” with different AEBP. Distillation to a 650 °F resid is done in accordance with ASTM (American Society for Testing and Materials) D 2892.\(^5\) In this 15/5 distillation under reflux, the distillation temperature is gradually increased and a series of distillate fractions removed; the pressure is then reduced to ~10 Torr to reach the AEBP of 650 °F without cracking.
the oil. The 650 °F bottoms is then charged into a second still where fractions are distilled in accordance with ASTM D 5236 down to pressures down to 0.1 Torr and AEBP of 1050 °F. Deeper distillations (1050–1300 °F, AEBP) are carried out at high vacuum with thin film evaporators with short vapor path lengths. Each short-path distillation produces a distillate and a bottoms; so multiple distillations are employed to generate the bottoms from 1050 to 1300 °F.

2.2 Range of Composition

With the exception of trace metals, the typical elemental composition of crude oil and of the corresponding residues varies only slightly over narrow limits (Table 1). However, the percentage of resid and percentage of sulfur in the resid differ widely among crudes (Table 2). Sulfur and nitrogen concentrations increase with the final boiling point of the resid fraction (Table 3). Although the numbers are not included in the tables, practically all the metals remain in the resid as well. Data for DISTAC distillation of the atmospheric residue from a heavy California crude (Kern River) show that the 1000 °F resid is nearly half the 775 °F resid and twice the 1300 °F resid (Table 4).

Extensive studies have been carried out to characterize the deep vacuum distillates. The resid produced in these studies show steady increases for S, N, and O from 775 to 1300 °F, with the exception of metals. While no metals are volatilized below 1050 °F, some metals do, however, distill into cuts between 1050 and 1300 °F. The results for the heterocyclics in the deep distillates demonstrate that the molecular types found in the lower boiling fractions are found in the resid, as well. Resid can be considered to fit a ball and string model where the balls are fused aromatic (or naphthenoaromatic) rings and the strings are carbon or heteroatom links between the rings. While the number of fused rings in the resid may be larger than in vacuum distillates or may contain metals absent from those fractions, most of the molecular types retain their characteristic reactivity. Therefore, many of the analyses determining the elemental and molecular-type composition of resid are a logical extension of those used for the vacuum distillates.

2.3 Physical Properties

The physical properties of residues make them a challenge for analysis (Table 5). Nothing can be seen or measured optically in residues because they are so dark. Residues may be lighter or heavier than water (API gravity D).

Measurements by ASTM tests show that resids vary in solubility (asphaltenes), viscosity, and tendency to form coke (carbon residue), all factors that complicate sample preparation.

3 DETERMINATION OF SULFUR IN PETROLEUM RESIDS

There are several standard methods suitable for measuring sulfur in resids. Sulfur can be measured directly in the resid matrix with X-ray fluorescence (XRF) or indirectly by titration or infrared detection (IR) after combustion to SO2. Standard analytical practice includes a number of variations on these two approaches. Other S-sensitive methods are not as well suited for resid.

3.1 X-ray Fluorescence

For XRF analysis, a sample is placed in a disposable cell with a thin Mylar® or polypropylene window, the cell placed (window down) over a fluorescence detector, and the contents of the cell irradiated at fixed angle by an X-ray tube with Cu, Rh or Cr target or a radioisotope (Fe-55).

There are several options for fluorescence detection. Samples containing 0.1–4.0% can be analyzed with a nondispersive (radioisotope) or energy dispersive detector (ASTM 4294). Instrument are calibrated frequently with sulfur in resid reference samples. While large amounts of heavy metals may interfere, the amount of iron, nickel and vanadium usually found in residual oils does not. The nondispersive and energy dispersive spectrometers are simple enough to be incorporated into portable instruments.

Lower levels can be measured at the sulfur Ka line at 5.373 Å with wavelength dispersive spectrometers (ASTM D 2622). Sulfur levels from 0.0003 to 5.3% can be measured directly after the addition of an internal standard. The background intensity measured at a recommended wavelength of 5.190 Å (5.437 Å for a Rh target) is subtracted from the peak intensity. The resultant net counting rate is then compared to a previously prepared calibration curve or equation to obtain the concentration of sulfur in mass percent.

3.2 High-temperature Combustion and SO2 Measurement

High-temperature combustion followed by SO2 detection offers an alternative fast method for determining sulfur in resids without matrix-matched standards. In the combustion techniques, samples are burned under controlled conditions and the mixture of SOx gases measured by titration or IR detection. ASTM D-1552 includes two types of combustion (tube furnace and induction furnaces) and two methods of measurement (iodate titration and IR detection of SO2).

To achieve complete combustion of the refractory resid (high boiling, viscous and tendency to form coke), the samples must be burned “smoothly” to SO2, i.e. without splatter, flash, or formation of coke. In the tube furnace combustion, a sample is weighed into a ceramic boat, MgO and V2O5 added as combustion accelerator, placed into the cool portion of the furnace, and a flow of oxygen established over the sample. The boat is then pushed
into the combustion zone set at 1371 °C (2500 °F) to produce SO$_x$ where SO$_2$ is ~97% SO$_2$. In the induction furnace combustion, samples are weighed into a ceramic crucible, covered with an inductor (powdered iron or tungsten) and accelerator (vanadium pentoxide). The crucible is covered and placed into an oxygen stream in the instrument where it is heated for 90 s by an induction coil.

For the titration measurement, the combustion products are passed into an absorber containing an acid solution of potassium iodide and starch indicator that is mounted on an autotitrator equipped with a photodetector. Initially, a faint blue color is established in the absorber solution by the addition of standard potassium iodate solution. As SO$_2$ is evolved, it bleaches the blue color and the autotitrator adds more iodate. The volume of standard iodate consumed during the combustion is a measure of the sulfur content of the sample.

For the IR measurement, the combustion products are passed through traps that scrub out CO$_2$, moisture and dust prior to IR absorption measurement. The area response of the IR absorbance is used to calculate the mass percent of sulfur for the sample weight. The IR calibration factor is determined using standards approximating the material to be analyzed. Accuracy is increased if standards bracketing the sample are also analyzed. The combustion techniques have comparable precision but are less convenient than XRF.(9)

3.3 Interferences

For XRF, errors in the sulfur determination can result when the elemental composition (excluding sulfur) of samples differs significantly from the standards. For example, differences in the carbon–hydrogen ratio in sample and calibration standards induce errors in the determination. Compensation is commonly made by the addition of an internal standard or use of a standard addition technique. Because the distance between the sample and detector affects the response, the Mylar® on the cell must be flat, the sample must be free of sediment (or diluted with solvents that do not induce asphaltenes formation), and “infinitely thick” (>15 mm) for consistent excitation. For combustion tests, the iodate titration can be affected by >1% chlorine and >0.1% nitrogen, while IR detection will tolerate somewhat higher concentrations.

3.4 S Speciation

Both wet chemical and instrumental techniques show that sulfides and thiophenes are the major sulfur types in resid. Characterization studies of the deep distillates suggest that both types are present within the multiring structures in atmospheric and vacuum resid. Iodate titration and iodine complex tests show that the fraction of sulfur as sulfide decreases as resid boiling point increases.(10,11) Roughly two-thirds of the sulfur in atmospheric resid is estimated to be thiophenic by a variety of techniques: iodate titration,(12) by NMR (nuclear magnetic resonance) measurements after derivatization,(13) excited X-ray absorption fine structure (EXAFS), (14) and X-ray absorption near edge spectrometry (XANES). (15) Selective reduction experiments suggest that the sulfides in resid exist in links between multiring structures as well as in the rings. (16) Sulfoxides detected by XPS (X-ray photoelectron spectrometry) may be limited to the thin layer (<10 molecules) sampled by this technique. Other advanced analytical techniques for elucidating the structure of sulfur species in various fossil resource materials have been reviewed. (17)

4 DETERMINATION OF NITROGEN IN PETROLEUM RESIDUE

4.1 Measurement Techniques

Nitrogen in resid is commonly measured by two techniques. The classic Dumas technique is used for samples containing >0.2% nitrogen; for samples containing less, nitrogen can be measured down to 0.004% by combustion and NO$_x$ chemiluminescence (ASTM D 5762). (15) Other N-measurement techniques are not well suited for the analysis of the forms and concentrations of N found in resid.

The Dumas technique is based on high temperature combustion, gas scrubbing, and reduction of nitrogen oxides for measurement as N$_2$ (ASTM D-5291 Method C). It is applicable to samples containing N between 0.1 and 50% N, irrespective of the form of nitrogen. In modern instruments, a sample is weighed into a tin capsule, combusted in oxygen (as O$_2$) at 1700 °C, and then the gases produced are swept through a train of gas-treating tubes with a helium carrier gas into a ballast reservoir. The gas treaters include chromic oxide (oxidizer) and silver-coated cobalt oxide (trap for halogens and sulfur). The scrubbed gases (CO$_2$, H$_2$O, NO$_x$) then are passed over copper at 650 °C to reduce the NO$_x$ gases to molecular N$_2$. This mixture is then carried through molecular sieves to remove water and through supported magnesium perchlorate to remove CO$_2$. The N$_2$ in the He gas is detected with a thermoelectricity detector.

In the chemiluminescence test for resid, a boat inlet system is used. The sample is placed on a boat at room temperature, the boat placed in a combustion tube, and a flow of oxygen–argon established. The boat is advanced into a high-temperature combustion tube where the nitrogen is oxidized to nitric oxide (NO) that
is then allowed to react with ozone creating an excited form of nitrogen dioxide.\(^5\) The light emitted when the excited \(\text{NO}_2^+\) decays is detected by a photomultiplier tube and the resulting time-integrated signal is a measure of the nitrogen contained in the sample. The detector is calibrated with model nitrogen compounds. Although the scope of the test can cover the 1–1000-ppm range the linearity of the detector is much more limited. Good laboratory practice would suggest using a calibration curve with nitrogen contents close to the range of the samples being analyzed.

4.2 Interferences

The Dumas and chemiluminescence methods are generally free of interference. Assuming that a representative sample has been taken and is within the calibration range of the methods, these analyses can be applied to most resids. As long as the sample is soluble in the mixed solvent used for the titration, the basic nitrogen in resids can also be measured routinely.

4.3 N Speciation

Deep HVGO (heavy vacuum gas oil) distillate data suggest that the most common nitrogen compound types in resid are pyrrole and pyridine benzologs.\(^7\) Dilute solutions of resid in deuterochloroform detect the pyrrolic evidence is found for alkyl or aromatic amines in resid. Deep HVGO data indicate the presence of amides in some resids. As long as the sample is soluble in the mixed solvent used for the titration, the basic nitrogen in resids can also be measured routinely.

5 DETERMINATION OF METALS IN PETROLEUM RESID

5.1 Measurement Techniques

Nickel and vanadium are present as organometallics in crudes at levels characteristic of their geochemical environment.\(^12\,1\) Although sodium and iron are also commonly measured in resid, these metals are more likely to be present as entrained brine (Na) or scale and soluble corrosion products (Fe). Other metals have been found in soluble form at trace levels (<0.1 ppm) and at higher levels in the form of entrained brine or corrosion products (scale). The metals in resid can be measured by a number of instrumental techniques, among them XRF, flame atomic absorption (FAA), graphite furnace atomic absorption (GFAA), inductively coupled plasma atomic emission spectrometry (ICPAES), and instrumental atomic emission spectrometry (IAES).

5.1.1 X-ray Fluorescence

The direct XRF techniques used for sulfur can be applied for Fe, Ni, and V if the metal concentrations are >10 ppm. XRF has poor sensitivity for Na. Although XRF has been reported to measure trace metals after acid digestion, precipitation and filtration, the results appear erroneously high.\(^24\)

5.1.2 Flame Atomic Absorption

In FAA, a sample is aspirated into a laminar acetylene–air or acetylene–nitrous oxide flame. The emission lines of the element to be measured (produced by a hollow cathode lamp) are focused through the flame into a spectrometer that measures the absorption of one of the characteristic lines. Corrections are made for background absorption using Zeeman effects or using broad band absorption from a deuterium lamp. Peak heights are measured and results quantified using standards prepared in similar matrix types.\(^25\)

Both direct and indirect FAA methods have been included in standard methods for the determination of Ni, V, Na, and Fe in crude oils and residual fuels by FAA (ASTM D 5863).\(^25\) In the direct method, samples are diluted to 5 to 20% in an organic solvent (xylene or tetralin), depending on the anticipated metal content. Separate analyses are made for sodium (589.0 nm), iron (248.3 nm), and nickel (232.0 nm) as they are aspirated directly into an air–acetylene flame. Concentrations are calculated from calibration curves prepared in the same manner using oil-soluble metals standards. Vanadium is analyzed at 318.4 nm using a nitrous oxide–acetylene flame with 15-ppm AI (oil-soluble standard) added as an ionization suppressant. The dilution, needed to minimize the effect of resid matrix, limits direct FAA to Ni, V, Na and Fe.

In contrast, the matrix is destroyed in the indirect method. Samples of 1 to 20 g can be wet ashed with sulfuric acid and the ash taken up into a dilute nitric acid solution. The solution is then analyzed for each element separately by FAA at the same wavelengths as the direct method. For vanadium, 250-ppm AI is added to suppress ionization and measurements made with a nitrous oxide–acetylene flame. Concentrations are determined from calibration curves in the same aqueous acid matrix.

5.1.3 Graphite Furnace Atomic Absorption

In GFAA, a hollow graphite tube furnace in an inert gas atmosphere is mounted in the optics of an atomic absorption spectrometer. A sample is introduced into
the furnace. The tube is heated (by electric resistance) through a sequence of drying (100–300 °C), ashing (600–1500 °C) and atomization (up to 3000 °C) stages. During the atomization stage, the peak height is measured and corrections made as in FAA. It is not possible to give specific heating cycles because the optimum conditions vary from element to element and between instrument designs. In indirect GFAA, where the samples are ashed prior to injection, the generic (aqueous-based) detection limits for GFAA are generally lower than for FAA, but actual values differ between instruments.\(^{(25)}\)

GFAA has also been applied to the direct analysis of metals in crude oils after dilution with toluene or xylene.\(^{(26)}\) Nickel measurements are routine; vanadium requires addition of some ashing aid (toluene sulfonic acid, for example) to avoid losses of vanadyl species by volatilization.\(^{(27)}\) Some trace metals have been measured by direct GFAA, but each analysis requires optimization of the heat cycles.

5.1.4 Instrumental Neutron Activation Analysis

INAA can be used to measure the metals as a survey technique.\(^{(28,29)}\) In INAA, a representative sample is sealed in an inert polyethylene capsule. The capsule is then pneumatically conveyed into a nuclear reactor where it is exposed to a high-intensity neutron flux (for example, \(5 \times 10^{12} \text{n cm}^{-2} \text{s}^{-1}\)) for a predetermined time (5 min to 8 h). After irradiation, the capsule is moved to a shielded detector until the background emission from short halflife isotopes has decreased sufficiently to allow the elements of interest to be detected. Radiation from the capsule is measured for 3 min to 10 h by a \(\gamma\)-ray spectrometer equipped with a lithium-drifted germanium crystal detector (Table 6).

NR = not reported. From Filby and Olsen.\(^{(28)}\)

5.1.5 Inductively Coupled Plasma Atomic Emission Spectrometry

In ICPAES, a sample solution is pumped into a 10000-K argon/oxygen plasma torch. At this temperature, all the organics are destroyed and the metals converted to excited atoms and ions. The emission from the torch is dispersed by a spectrometer onto an array of photodetectors positioned to measure one of characteristic atomic emission lines of the selected elements. Results are determined from calibration curves using external standards. Each ICPAES spectrometer is unique in design, selected wavelengths, and computer capabilities; suggested emission wavelengths are given in standard methods (ASTM D 5708).\(^{(25)}\) All measured emission peaks are referenced to a specific element added as internal reference.

In ASTM D5708 (Method A),\(^{(5)}\) ICPAES is used in a direct method that measures Ni, V, and Fe. In the method, a sample is diluted to 10% (w/w) with xylene or tetralin. Results are determined from calibration curves using standards in a white oil diluted with the same dilution solvent. The direct ICPAES method is modified slightly for use in measuring trace metals (Ag, Al, B, Ba, Ca, Cd, Cr, Cu, Fe, Mg, Mn, Mo, Na, Ni, P, Pb, Si, Sn, Ti, V, and Zn). A sample is blended with an internal reference (Co) to correct for viscosity effects. Typical working ranges are in the 0.05–10 ppm range.

In the indirect ASTM test for Ni, V, Fe, and Na (D5708-Method B),\(^{(5)}\) resid samples are combined with sulfuric acid in a beaker and heated to dryness on a hot plate to char the sample and convert the metals to sulfate salts. The beaker is then placed in a muffle furnace at 525 °C overnight to burn off the char. The inorganic residue is digested with nitric acid and evaporated to incipient dryness. The contents of the beaker are then dissolved in dilute nitric or hydrochloric acid, the solution made to volume, and the metals quantified by ICPAES using aqueous calibration standards. Detection limits vary with the size of sample used and the spectroscopic sensitivity of each metal to be measured. Metals measured by this technique differ slightly from the direct technique (Al, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Sb, Ti, V, Y, Zn, and Zr).

5.1.6 Inductively Coupled Plasma Mass Spectrometry

Inductively coupled plasma (ICP) capabilities have been expanded and detection limits lowered by the introduction of inductively coupled plasma mass spectrometry (ICPMS).\(^{(30,31)}\) The latter combines ICP excitation with mass spectrometric detection. In this mode, the ICP torch generates a cloud of ions that are accelerated into a mass spectrometer that resolves the excited atoms. Because the torch also destroys the sample matrix, ICPMS can be applied directly to oil samples dissolved...
in xylene. In addition to dilution with solvent, resid samples have been analyzed by ICPMS in the form of aqueous microemulsions. Both internal standard (Bi, Sc, etc.) and standard addition techniques have been used for quantification. If samples are ashed and analyzed in diluent aqueous acid, the ICP methods have even better sensitivity and are less subject to interference. However, care must be taken to avoid Cl (brine salts, methylene chloride or HCl) because the CIO formed in the torch interferes with the measurement of V at mass 51.

5.1.7 Choice of Metals Method

Trace metals can be measured in resid by many of the above techniques. Nickel and vanadium in resids can be determined rapidly by XRF at levels above 10 ppm. Many of the FAA and GFAA techniques developed for individual trace elements in the 1970s are still in use. Where applicable, direct GFAA affords the fastest technique for determining an individual element. For greater accuracy and sensitivity, indirect FAA and GFAA remain the methods of choice for individual elements.

Multielement survey data can be collected on resid by INAA and ICP techniques that use expensive specialized instrumentation. ICP methods have largely supplanted INAA for survey measurements of trace elements because they have lower detection limits for most elements. Direct ICPAES can be used to rapidly screen soluble metals; the indirect version can be more sensitive and can quantify suspended metals. The same restrictions apply to ICPMS which has several orders of magnitude more sensitivity for many elements. INAA and ICP results for Fe, Ni, and V are in excellent agreement with other techniques. However, the advantages of INAA (multielement, simplicity of sample preparation, minimal matrix effects, few interferences) are balanced by long analysis times caused by decay periods and specialized training needed for working with reactor and radioactivity.

5.2 Sample Preparation

5.2.1 Sampling

Crude oils are produced with varying amounts of water (actually salt-rich brines) and sediment; traded crude oils always carry some portion of these nonvolatile impurities. Distillation leaves sediment and (now dry) salts in the resid. After desalting, uptake of corrosion scale and addition of process aids, the refinery resid differs from the laboratory resid obtained by distillation of a crude oil that retains the sediment and dry salts.

In comparison with Ni and V, trace metal analyses show wide discrepancies. The variations among reported values appear to be related to sample homogeneity and preparation technique rather than the detection system. This has been reinforced by a systematic study of trace metals in whole crudes that shows natural metals concentrations two orders of magnitude lower than reported elsewhere. A statistical evaluation of the data scatter suggests that many of the trace metals are associated with contamination in transportation or with suspended sediment and water.

For accurate trace metal analyses of a submitted sample, relatively large portions of resid should be taken as a heterogeneous material after thorough mixing. Resid can be mixed after heating to a free flowing liquid or as a dry powder after freeze-fracturing or freeze drying.

5.2.2 Direct Methods

The physical properties of resid can play a significant role in the direct analysis of metals in resid. Inherently, the direct methods assume that the metals are homogeneously distributed in the resid sample. Because the residuals are so dark, it is difficult to determine if sediments are present. If the metal is present as particulate (scale or salts from entrained brine), the direct techniques can give erroneous results. High results may be obtained in XRF if a metal-rich sediment settles onto the Mylar® window in the test cell; low results may occur if particulates escape the atomic absorption flame or ICPAES torch. Variability in direct analyses by ICP methods can arise from factors that influence the sample flow into the ionization region, especially viscosity, surfactants and choice of solvent, and calibration should be done with oils that closely match the sample matrix.

As noted above, metals can be lost in the dry ashing provided as part of the GFAA cycle. Published detection limits for aqueous solutions may not be achievable by direct GFAA analysis of resid samples. The severe ashing conditions required to minimize background interference from sediments can volatilize some metals. This is particularly true of the Ni and V porphyrins in resids, but can also apply to the more volatile metals such as mercury, selenium, arsenic, cadmium, antimony and lead. To reduce the severity of ashing conditions and eliminate metals loss, homogenous ashing aids (such as p-xycenesulfonic acid) can be added to the diluent.

The materials accelerate the destruction of the resid allowing lower ashing temperatures and also convert the metals into a microsulfated ash, i.e. sulfates and oxides that are less volatile than indigenous metal compound types.

5.2.3 Indirect Methods

Most heavy metals are not lost in wet ashing of resid. The exceptions, metals not readily oxidized or inherently
volatile as the oxide (Hg, Se, As, etc.), have been studied separately. The initial addition of sulfuric acid prevents losses of some metals if chlorides are present, for example V as VOCl₃. The sample should be well mixed with sulfuric acid and heated gently at first to avoid splatter. Numerous variations have been suggested for ashing samples for trace metals including alternate oxidizing agents, different acids for dissolution, and reagents for fluxing the sulfated ash. Microwave ashing has been substituted for the sample preparation of resid samples for metals analyses. In microwave ashing, the resid is combined with oxidizing acids (sulfuric, nitric, perchloric or mixtures thereof), sealed in Teflon™ vessel, and heated in a microwave oven for a brief period. The resulting solutions are washed from the vessel with aqueous acid, an internal standard added, and made up to volume. Because it uses concentrated heating in a closed vessel, microwave ashing is faster and less subject to contamination than sulfated ashing. On the other hand, their microwave techniques are limited to small samples and care has to be taken to avoid explosions with the sealed vessel. Thus, sulfated ashing, is preferred for routine analyses because it requires less technique and no specialized equipment.

5.3 Metal Speciation

The consistency of the Ni and V results among techniques demonstrates that these elements are homogeneously dispersed in the colloidal resid. A portion of the metals can be measured by the Soret bands characteristic of porphyrins in the ultraviolet–visible spectra. Although a larger fraction of the metals are described as “nonporphyrin” structures, X-ray absorption fine structure (XAFS) analyses show that all the Ni and V resid is in molecular environments similar to those in porphyrins. Thus, the nonporphyrins appear to be mixtures of closely related tetrapyrrole analogs. This direct spectroscopic evidence is more compelling than the indirect data (reactivity, size exclusion chromatography, ESR (electron spin resonance), etc.) from which alternate structures have been inferred. The lack of a Soret band for these metals may be rationalized by (i) molecular association of tetrapyrrole structures with electron-rich aromatics or heteroaromatics; (ii) a mixture of numerous isomeric porphyrin homologs with overlapping spectra; (iii) molecules with extended conjugation (benzoporphyrins), or a combination of all these.

Among the trace elements, Fe in resid can appear in both soluble (indigenous naphthenates and corrosion products) and insoluble (scale and iron sulfide) forms. For accurate total iron measurements, indirect techniques should be used on well-mixed samples. Other trace metals in resid may also be present in either soluble or suspended form. The suspended forms, arising from brine salts, probably contribute more to the trace metal load than soluble metals. The latter are generally naphthenate soaps of basic metals (groups I, II, VIII). Traces of elements that can form organometallics (As, Hg, Se, etc.) are found in crude, but rarely survive distillation.

6 COMPARISON WITH OTHER “HEAVY OIL” MATRICES

Resids are often compared with other viscous black oils that are rich in trace metals and heteroatoms. Although some of these “oils” are extracts and others are pyrolyzates, they are lumped together because they represent a major hydrocarbon resource that challenges conventional crude oil processing. In most cases, the methods used for the analysis of resids can be applied to these alternate “heavy oils”. The following briefly notes the characteristics of each type and the unique difficulties that each presents for the methods.

The elemental composition of oil sand bitumen falls generally into the range of petroleum resid with 1–10% S, 0.4–1.0% N and nickel and vanadium contents hundreds or thousands of parts per million. The higher molecular weight, viscous nature of these oils presents basically the same challenges as found for resids, that is, taking representative samples, avoiding solvent precipitation, and preventing coke formation prior to measurement. The analyses of S, N, Ni, V, and Fe in bitumen, extra heavy oils and tars have been widely reported. Classic combustion techniques are routinely applied for S and N. Direct INAA or indirect ICPAES are favored for metals.

Most of the techniques used for petroleum resids can be applied to shale oils with adjustment of sample sizes to keep within the instrumental calibration range.

Table 7 Heteroatom content of some raw shale oils determined by different processes.

Shale oils are rich in olefins, diolefins and nitrogen. The nitrogen-compound types that best survive the retorting conditions are nitriles, amides and pyrroles. In presence of air, the latter combine readily with the olefinics to form sediments. Thus for quantitative analyses, shale oil samples must be protected from air. The boiling point distribution of heteroatoms of retort oils differs from petroleum resid. As a cracked product, the shale oil exhibits the decrease in sulfur concentration with boiling point while the concentration of nitrogen increases. Oxygen levels are typically higher than resid, but lower than coal liquids. Crude shale oils contain soluble forms of iron, nickel, and arsenic that can be measured by resid techniques. Care must be taken to avoid losses of arsenic in volatile forms, however. Heteroatom contents of shale oils from a variety of sources show variability (Table 7):

1 INTRODUCTION

The goal of any manufacturing process is to make acceptable products in an economical fashion. To do this requires timely information about raw materials, material in process and product quality. It is the role of on-line analytical instrumentation in providing some of this information on crude oil, gasoline, and diesel fuel that will be addressed in this section.

2 ON-LINE VERSUS LABORATORY INSTRUMENTATION

Laboratory instrumentation sits in an environmentally controlled atmosphere and is operated by skilled people to provide information on samples collected from the process. The goal of both the on-line instrument and laboratory instruments sounds the same, that is, to provide information, but the conditions they must operate in are very different. The laboratory instrument has a skilled operator, whereas the on-line instrument must operate on its own. The laboratory instrument works on a sample that is extracted from the process line and normally cooled to room temperature and reduced to atmospheric pressure. The on-line instrument takes its own sample and works with it at line pressure and usually at line temperature.

If any adjustments are required, the on-line system must make them as no operator is involved. This, of course, must be done by the sample system but the on-line instrument dictates what the sample system must do. One question that arises frequently is the need for temperature control of the sample. Near-infrared (NIR) spectroscopy is a tool which counts molecular bonds within the sample. As the temperature changes the number of molecules within a given path length changes and therefore the spectrum changes. In a system with very little hydrogen bonding, most of the changes can be accounted for with just the change in density. If hydrogen bonding exists, such as with water or alcohol, major changes in the spectra are noted with temperature differences. This need for temperature control can become a significant item for on-line instrumentation and is normally ignored in the laboratory because everything is at the same temperature, the temperature of the room.

3 NEAR-INFRARED SPECTROSCOPY – WHAT IS IT? OVERTONES?

Light can interact with matter in several ways:

1. Simple reflection – we see that every morning in the mirror.
2. Refraction – light as it changes mediums changes direction, for example, going from air into water (our eye glasses are shaped by this principle).
3. Ultraviolet light can be absorbed by certain molecules and has enough energy to move electrons into an excited state.
4. Infrared (IR) light can excite, stretching and bending the bonds that are dipolar.

In the NIR region of the spectrum, that band of wavelengths between visible light and the IR, or wavelengths from 700 nm to 3000 nm, light is able to excite overtones and combinations of some of the molecular bonds that are excited by the IR. The only significant absorbencies in the NIR are due to the hydrogen–X bonds where X is a heavier atom. Therefore, organic compounds where we have bonds between hydrogen and carbon, H–C, show bonds clearly in the NIR region. From the above, one might
think that all H–C bonds absorb at the same frequency and with the same intensity. However, this is not the case: just as in the IR range, there are many different bonds, depending on what else is attached to the carbon. For example, methyl bonds will differ from methylene bonds, which will be different again from aromatic hydrogen bonds.

NIR spectroscopy then makes use of the overtones and combination bands to analyze compounds in both quantitative and qualitative terms. Because of the complexity of the spectrum the qualitative aspect of NIR is played down but is used in judging raw materials for suitability in some manufacturing processes. By far the biggest use of NIR is in the quantitative area, not only for chemical make-up of the sample, but also for the physical properties of that sample such as boiling point.

How can the boiling point of a liquid be determined by shining light through it? From elementary physical chemistry we know that the boiling point of a mixture is determined by the mole fraction of each component in the mixture multiplied by the boiling point of each component. A mixture is not a static system. As it starts to boil, certain compounds evaporate first; this changes the composition so now the boiling point is higher. This process continues until all of the liquid has boiled. What could be done is to determine each component in the liquid, calculate its mole fraction and therefore its influence on the boiling point. By summing over all these components the boiling curve of the liquid could be determined. The NIR approach skips the step of identifying each component in the mixture but based on “experience” finds a pattern which will predict the boiling points of the liquid. This “experience” is called a model—a mathematical relationship between absorbencies at various wavelengths and the boiling points of the liquid. This “modeling” is one of the most powerful and frustrating aspects of NIR spectroscopy. It is frustrating in the sense that although the human brain cannot process the NIR spectrum into the underlying components, a computer, “trained” using various statistical methods, can. The methods start with a “training set”. The spectra are collected for a set of samples which are similar to the samples expected to be used by the NIR instrument. Correlations are found between the wavelengths and associated absorbencies with the properties of interest. If these correlations involve very few wavelengths then we can use a method called multiple linear regression (MLR) to develop a “model” between the spectrum and the property of interest. More commonly many wavelengths are involved and we use methods such as partial least squares (PLS) or principal component regression (PCR). Both methods can use the entire spectrum and the difference is that PLS uses correlations between the property of interest and the spectrum to find the best fit and PCR uses the biggest spectral differences and tries to find correlations. (I have used PLS because that has worked the best for me where I have tested various methods.) Whatever mathematical tool is used, we call the resulting equation between the spectrum and the property of interest a model. One can apply various models to the same spectrum to determine various properties. In one refinery we are using 14 models to “predict” or measure the properties of the gasoline flowing through the NIR.

3.1 Warning

The above tools are extremely powerful and correlations will be found for any property of interest regardless of spectral information. Models should always be tested on a new set of samples, called the verification set, before the model is used. Since this new set of materials has not previously been analyzed by the spectrometer computer system, the results should indicate what will happen with future production samples. Note that the system can only measure samples within the calibration range of the instrument. If samples are outside the calibration range a new “model” must be constructed to incorporate the new sample types. Sometimes this involves a totally new model and sometimes the old model can be modified to include the new information. If the process has permanently changed, I recommend building a new model. If the old model did not cover the total range—then extend the model. I have seen different models used for winter and summer grade gasoline, for example, as well as a different model for each grade of gasoline.

3.2 Assessment of the Instrument

Why would one use NIR with the computer algorithms when IR is available? The biggest arguments for the use of NIR for liquid samples are: that sources are more stable; the detectors are easier to work with and more stable; windows are more sturdy (glass vs. salt plates); the path lengths for liquids are much more reasonable (mm and cm in the NIR compared with 0.1 mm or less in the IR); and fiberoptics are readily available in the NIR, at lower cost compared to IR fibers. The IR has a major advantage in the laboratory setting in ease of interpretation of the data; however, in the process environment, where very similar samples are seen minute after minute, for many days, it is the quantitative ability of the NIR that wins over the qualitative advantages of the IR region.

The statement that fiberoptics are readily available in the NIR region needs comment. There are many vendors who supply fibers for the communication industry that operate in the NIR region. In the communication industry the signal is either off or on; by contrast, for the analyzer industry we need to quantitate the size of the signal. In the
communication industry, certain wavelengths are chosen which fit well with the existing fibers, but in the analyzer industry we are using the wavelength range. The point is that fibers designed for the communication industry may not, or more probably will not, work for the analyzer.

3.3 Examples of Problems with Fiberoptics and How to Address Them

Figure 1 is a superimposition of two different pictures. In each case we have 10 m of fiber connected to a power meter. The difference is that at the bottom the fiberoptic coil is covered with black felt. The readings on the power meter tell the story: on the top where light is hitting the fiber, the reading is 389.7 and on the bottom with the fiber covered, the reading is 8.8. What is happening? Light is going through the fiber jacket and coupling into the fiber and that is what the power meter is reading. Once the problem is defined, there is an easy solution: to make the jacket out of material that does not transmit light in this region of the spectrum.

The following is taken from a 1992 Eastern Analytical Symposium talk by G.H. Vickers of Amoco.

Figure 2 shows a standard drawing of an optical fiber. The assumption is that the light turns at the interface between the core and cladding and does not penetrate into the cladding. Figure 3 shows the spectrum of 10 m of plastic-clad silica fiber. The large absorbances are from the plastic cladding CH bands. This fiber is not usable in the NIR region. Figure 4 shows the spectra of a silica-clad, low OH, silica fiber with a Tefzel® jacket as a function of temperature. Note the large changes around 1400 nm. This is due to the change in the hydrogen bonding around the few remaining OH groups in the silica fiber. Also note the bands around 1250 nm and others of similar size. They are due to the CH bonds in the Tefzel® jacket. The cladding jacket is acting like a secondary fiber and becomes a plastic-clad silica fiber. How can this be avoided? Use a jacket material of high index of refraction to extract the cladding modes. The success of this is shown in Figure 5, where we have a silica fiber with a

\[
\frac{\beta}{\gamma} \leq \frac{n_2}{n_1} \\
\alpha \geq \sin^{-1} \left( \frac{n_2 - n_0}{n_0} \right)^{1/2}
\]

Figure 2 Total internal reflection in an optical fiber.

Figure 3 Absorbance spectrum for a plastic-clad silica fiber.
PETROLEUM AND LIQUID FOSSIL FUELS ANALYSIS

Figure 4 Absorbance spectra of a silica-clad silica fiber with Tefzel® jacket at temperatures from 5 °F to 125 °F.

Figure 5 Absorbance spectra of a silica fiber clad with polyimide at temperatures from 5 °F to 125 °F.

silica cladding jacket with polyimide. Note the scale: other than the 1400 water peak, the spectra show changes of less than 0.005 AU. To eliminate this remaining difference we coil the fiber inside the jacket to allow for differences in thermal expansion of the fiber and the jacket as the temperature changes. In other words for fiberoptics to be usable in NIR requires some thought and understanding of the physics of the fiber. Unfortunately, all of the things mentioned to make the fiber useful add to the cost of the fiber.

It was mentioned previously that the optical path length through the cell in the NIR has a range from millimeters to centimeters. The NIR spectral region can be further subdivided according to the C—H vibration overtone. The higher the overtone the shorter the wavelength and the longer the path length for an equivalent absorbance. In general we can use a path length about a factor of 10 longer for each overtone. Therefore, in the first overtone region the path length is about 1 mm, in the second about 1 cm, in the third about 10 cm. With the 10-cm path the sample needs to be free of scattering particles or that effect will dominate the spectrum. There is another problem with the third overtone which must be discussed: interference from the ultraviolet and visible spectrum.

Certainly, most crude oil is black, but not all. The black color is due to the asphaltenes that are present in most crude oils. The peak absorbence of asphaltene is down in the ultraviolet part of the spectrum but the tail of the peak is so large that it extends through the visible and the third overtone of the NIR. However, if one examines the second overtone region, information on the olefin, aromatic and saturate content of the crude oil is available. Some work has been done trying to measure the sulfur and metals content of the crude oil but the results are questionable.

In the mid-1980s, Dr Jim Callis (University of Washington, as part of a project for the Center of Process Analytical Chemistry, CPAC) showed that octane numbers of gasoline (see section 3.4) could be determined from the NIR spectrum. The oil companies that were part of CPAC were skeptical of Dr Callis’ results but realized the enormous impact they could have if proved to be real. Several companies undertook their own projects to test Dr Callis’ work. The private work confirmed his original data and showed that the octane numbers could be obtained in all three overtones. However, additional effort also showed the sensitivity of the results to wavelength long-term reproducibility. By that I mean, if a model was developed and the spectrometer’s wavelength axis drifted, the model’s results were meaningless. In order to avoid the inherited drift in the moving grating spectrometers, two avenues were pursued. BP and Bomen worked together to develop the TOP-NIR which is a Fourier transform (FT)–NIR instrument. EXXON and Analect Instruments also developed an FT–NIR approach. Amoco and Perkin-Elmer developed a third overtone diode array system, the PIONIR 1024. Both the FT and the diode array approaches avoid the variation caused by the moving grating but introduce other problems which must be accounted for. With the diode array concept, dimensional stability is vital – hence the spectrograph temperature is controlled within 0.5 °C as the outside temperature varies from −40 °C to 50 °C on the PIONIR 1024. With the FT approach, mirror movement is referenced to a laser wavelength to ensure stability. All three systems have proprietary systems built in to give the required stability on the wavelength and absorbance axis to make the octane measurements.

A report in Oil & Gas Process International, 1997, by Kjell Arne Ulrund of Statoil, Norway, reports that
in addition to the octane numbers, they are measuring the MTBE (methyl tertiary butyl ether) concentration, olefins, benzene, initial boiling point, final boiling point and distillation evaporated at 70, 100 and 180°C, every minute, using the PIONIR 1024. This system allows the operators, either human or computer, to optimize the gasoline blends using materials available in the refinery. The speed of the data allows on-line blending into ships for transport of the fuel.

3.4 Octane Numbers

There are three octane numbers: the Research Octane Number (RON), the Motor Octane Number (MON), and the Pump Octane Number (PON), which is the average of RON and MON. The traditional way to determine the RON and MON is with an engine and compare when the test fuel “knocks” in the engine compared to the standard. The standard is a blend, for MON, of iso-octane (2, 2, 4-trimethylpentane, octane number 100) and n-heptane (octane number 0). The MON is determined by finding a composition of iso-octane and n-heptane that knocks the same as the test fuel under the conditions of the test. It reflects the normal engine requirements at idle conditions. The RON is again determined by an engine test but the conditions simulate an engine under load. More severe conditions require a higher standard and test fuel "knocks" in the engine compared to the standard. The RON is determined by an engine test but the conditions simulate an engine under load. More severe conditions require a higher standard and that is toluene, octane number 113. The RON then finds the ratio of n-heptane, iso-octane and toluene that has the same knock properties as the test fuel under these new conditions.

Both the RON and MON tests have significant reproducibility problems and require highly trained operators to obtain consistent results. (I have been told that it takes about five years to train someone to correctly run the knock engines.)

Since the octane properties are related to the chemical composition of the fuel, maybe it is not too surprising that the octane number could be determined by the NIR. However, when one considers that a typical gasoline is a mixture of over 250 compounds it is amazing that a 5 to 10 factor PLS will allow determination of the octane number from the NIR spectrum.

3.5 Determination of Methyl Tertiary Butyl Ether

The standard way to measure MTBE in gasoline is with a long, 40-min, gas chromatography (GC) procedure. A 40-min analysis may be acceptable in a laboratory but consider a refinery that is blending 1 million gallons per hour (a single large gasoline refinery). What is that refinery to do? It must put in at least the minimum legal level of MTBE. If the GC analysis is not available until 40 min after analyzing, the refinery must hold that 1 million gallons of gasoline waiting for results or put in enough MTBE to make sure it has the legal minimum. With the NIR report results every minute, the “excess” MTBE can be reduced.

How can the NIR measure the ether concentration? Because of the electronegativity of the oxygen, the hydrogens on the carbon adjacent to the oxygen will absorb light at a slightly lower wavelength (higher energy). It is that shift which can be measured.

3.6 Olefins

Olefins are very reactive compounds and at very high concentrations are used to make polymers, e.g. polyethylene. In gasoline they are blamed for gum formation in the fuel system, and as components in the formation of smog if they escape from the system.

The standard method for determination is called fluorescence indication analysis (FIA) (do not confuse with flow injection analysis, also referred to as FIA). The FIA procedure involves flushing the sample down a silica gel column which has been impregnated with indicators; as the gasoline flows through the column, colored bands will show the paraffins, isoparaffins, aromatics, naphthaphenes, and olefins in the gasoline. Again, this is a very slow test that is nonrepeatable. Factors associated with the lack of repeatability are the column packing, flow through the column, sample size, and the indicator preparation. This is very different from shining light through the sample, as is done with the NIR method.

4 ACCURACY AND REPEATABILITY

Several times the standard tests have been referred to as nonrepeatable, yet these are the standards which are used to calibrate the NIR. How can the NIR do better? There are two different issues to consider: repeatability and accuracy.

The NIR is extremely repeatable in determining the absorbance vs. wavelength, the spectrum values, on an acceptable unit. The model which coverts such data to information, such as octane number, is just a multiplier, a set of numbers. Hence it is totally repeatable. Therefore, the NIR system will give the same answers on the same sample regardless of how many times it is run.
